Owing to the increased weight of the trains, and the greater span of railway bridges, it was afterwards found necessary to strengthen this form of bridge, by the addition of arches on the sides of the trusses. This "Improved Howe Truss," as it was usually called, came into general use. A bridge on this plan was described, which was built for a double line on the Philadelphia and Reading Railway, where it was subject to to the heaviest traffic in America, the coal conveyed over it alone exceeding 5,000 tons daily, besides the ordinary passenger and goods trains. This bridge had a clear span of 160 ft. There were three trusses, each 23 ft. deep, and six arches. The sectional area of the three upper chords was 1,215 square inches, of the bottom chords 1,620 square inches, and of the six arches 1,530 square inches. The arches were formed of the best pine, in pieces about 24 ft. long by 4¼ in. wide and 15 in. deep. Timber arches had not unfrequently been built of pieces 6 in. square; but very rarely of laminated plank, in the manner formerly practised in England. Supposing a load of three tons per lineal foot, including the weight of the structure itself, to be equally distributed over this bridge, and to be borne both by the upper chords and the arches, then the compressive strain per square inch would be 292 lbs. on the former, and 287 lbs. on the latter; while if sustained by the arches alone, the pressure would only amount to 368 lbs. per square inch. As American engineers usually considered 900 lbs. per square inch as the safe limit of compression on timber framing, the strength of this bridge appeared, by calculation, to be greatly in excess of what might be deemed necessary.

The approximate quantities of materials in this bridge, exclusive of the roof, were per lineal foot, 58 cubic feet of timber, 270 lbs. of wrought iron, and 76 lbs. of cast iron; and the cost of the superstructure amounted to £10 3s. per lineal foot.

These bridges were usually built with a camber of about 1 foot; but owing to decay at the joints, and the unseasoned state of the timber when framed, they soon deflected, and did not last in good condition longer than from twelve to fifteen years. When, however, they were roofed in and boarded at the sides, and were properly cared for, their duration might be taken at twenty-five years.

Some American engineers did not approve of the arch in combination with the truss, believing that a structure composed of two systems, neither of which was strong enough by itself, was wrong in principle, and that it was almost impossible so to proportion the strains as to make each system bear its due share. These engineers thought it better, either to add to the truss the material used in the arch, and to have a light truss merely to stiffen the roadway.

Timber-bridge building had become a special branch of engineering in America, and one firm alone—that of Mr. D. C. McCallum—had constructed 15 miles on length of bridges upon different railways, in spans varying from 30 ft. to 260 ft. These bridges were built on what was termed the "Inflexible Arched Truss" principle; and a description was given of a bridge, for a single line of railway, 200 ft. span, of which several had been erected in the States of New York, Ohio, and Mississippi. The principal dimensions were—total length, 210 ft.; span, 200 ft.; depth of truss in the centre, 26 ft., and at the ends, 21 ft. The arched tops of the two trusses had together a sectional area of 814 square inches, and the two bottom chords of 468 square inches. There were four main braces, which projected 32 ft. from the piers, having a sectional area of 704 square inches on each side. The posts, of which there was a double row, inserted between the chords, varied from 9 in. by 13 in. at the abutments to 9 in. by 6 in. at the centre; the counter-braces being 9 in. by 6 in. throughout. Special attention was directed to the manner in which the bottom chords were scarfed, by long splicing pieces and combination keys, so as to prevent them, as much as possible, from stretching. The spur arch braces also transferred the load directly unto the abutments, by which the span was directly reduced to 136 ft., so far as the strain on the truss was concerned. This bridge contained 7,360 cubic feet of timber, 6,958 lbs. of wrought iron, and 5,997 lbs. of cast iron. Its total cost was £5 4s. per lineal foot; the rough timber being delivered on the site of the works at one shilling per cubic foot. The total weight, including the permanent way, was 109 tons, and with an additional load of 205 tons, equally distributed, the pressure on the arched top would be 862 lbs., and the tension on the bottom chords would be 1,500 lbs. per square inch. With an actual load of nearly one ton per lineal foot, this bridge deflected nearly three-quarters of an inch, previous to the adjustment of the counter braces; these were then screwed up, and the load was removed, when the permanent deflection was found to be nearly five-eighths of an inch.

Several railway swing bridges, of 120 ft. span, had been constructed of timber by Mr McCallum, and the principal dimensions, as well as detailed drawings, of one on a similar plan, proposed to be erected over the Mississippi river, at Clinton, Ohio, were given. A McCallum common road bridge, of 150 ft. span, was then described; and it was stated that the quantity of timber in such a bridge, 20 ft. in width, did not exceed 23 cubic ft. per lineal foot, its entire cost amounting only to £3 2s. 6d. per lineal foot, the rough timber delivered on the ground being estimated at 9d. per cubic foot.

As an illustration of the adaptation of the Howe Truss for large roofs, a description was given of that erected at the Dunkirk station of the New York and Erie Railway, the span of which was 80 ft. This roof was chiefly remarkable for the lightness of the scantlings, only two pieces of timber being as large as 6 in. by 7 in., and most of them were about 5 in. by 7 in. A principal of this roof contained 280 cubic ft., and would cost, at the ordinary price for timber framing, including erection, about £36.

In conclusion, the author expressed the hope that these specimens of timber work, the result of many years' experience, and the adaptation of the only available resources of a new and comparatively poor country, would be found interesting; as, whatever their merits or faults, the bridges had undoubtedly produced good practical results, and would bear investigation.

The second paper read was "On the Reconstruction of the Dinting and the Mottram Viaducts," by Mr. W. Fairbairn, F.R.S., M. Inst. C.E.

After alluding to the many advantages resulting from the application of a tenacious but flexible material, like wrought-iron, either in the tubular girder, or other forms in which it was now employed, as being probably the most suitable for bridges and viaducts of great width and span, where strength and durability were required, the author remarked, that at the present time there did not appear to exist any inducement on the score of economy, for the introduction of a perishable material, such as timber, into structures intended to be of a permanent character. He then briefly described the original condition of the Dinting and Mottram Viaducts, on the Sheffield and Manchester Railway, which were erected in the year 1843-44, under the direction of the late Mr. Joseph Locke The former consisted of five arches of 125 ft. span, the latter of one arch of 150ft., and of two of 125ft. span, constructed of timber ribs on the laminated principle. As was generally the case with similar structures, within ten or twelve years after their erection, the timber was so much decayed as to endanger their security, and to render considerable repairs indispensable. It was then contemplated to substitute iron work, but this step was not finally determined upon until the year 1858, when the viaducts were again in such a state as to alarm the passengers. It was stated that the restored portions for each viaduct consisted of two longitudinal and continuous tubular iron girders, fixed to the middle piers, and free to expand and contract in the direction of the abutments. To the top of these girders iron cross beams were rivetted, on which were laid the longitudinal sleepers for supporting the rails. There was nothing new in the construction of the girders. They were one-thirteenth of the span in depth, and the areas of the top and bottom flanges were in the proportion of 7 to 6, the breaking weight, equally distributed, amounting to 12·58 tons per lineal foot. The chief novelty was in the mode of erection, and in the method of substituting iron for wood; the directors of the railway company having insisted on the condition that the traffic should not be interrupted during the progress of the works. Several plans were proposed, but that which was ultimately adopted was to construct the girders on the old existing platforms, to cut down the piers and the abutments, and then, by a simple mechanical apparatus, first to suspend and afterwards to lower the girders into their places. A strong wooden frame, about 16 ft. high, was erected on the pier at each end of the girder, and on the top of this was inserted a cast-iron plate, with a hole in the centre, through which a square-threaded screw, 4½ in. in diameter, was passed. Centred on this screw, and resting on the cast-iron plate, was a bevel wheel, which received motion from a pinion, in connection with spur gearing, worked by crank handles in the ordinary manner. On the lower end of the large screw was forged an eye, to receive a cross-bar, having links at each extremity, which hooked under the angle irons at the sides of the girder. With six men at the handles, each girder was raised and lowered into its place in one hour. When one line of girders was thus completed—the whole of the traffic having in the meanwhile been carried by a single road—a temporary way was laid upon this line of girders, and the traffic was transferred to it. The girders on the other side of the viaduct were next constructed, and when they were finished, the iron cross-beams were rivetted to these girders, and the permanent way for this line was made good. The trains were again passed on to this road, the permanent way on the other side was laid, the timber arches and the framing were removed, and the viaduct was complete.

In consequence of the marriage of his Royal Highness the Prince of Wales having been fixed for Tuesday, the 10th of March, it was resolved that there should not be any meeting of the institution on the evening of that day.

Meetings for the Week.

Mon.—*Royal Inst.*, General Monthly Meeting, at 2 p.m.
Soc. of Engineers, "On the Relation between the Safe Load and the ultimate Strength of Iron," by Mr. Zerah Colburn, at 7 p.m.
Tues.—*Inst. Civil Engineers*, "The Perennial and Flood Waters of the Upper Thames," by Rev. J. C. Clutterbuck, M.A., at 8 p.m.
Royal Inst., "On Animal Mechanics," by Professor Marshall, at 3 p.m.
Wed.—*London Inst.*, "On the Zoology of Warm-Blooded Vertebrata," by C. C. Blake, Esq., at 7 p.m.
Soc. of Arts, "On the Construction of Twin Screw Steam Ships," by Capt. T. E. Symonds, R.N., at 8 p.m.
Geological Soc., 1, "On the Permian Rocks of the North-Eastern parts of Bohemia," by Sir R. I. Murchison, K.C.B., &c. 2, "On the Correlation of the several divisions of the Inferior Oolite in the Middle and South of England, by H. B. Hall, Esq., at 8 p.m.
Thur.—*Antiquaries*, at 8.30 p.m.
Royal Inst., "On Chemical Affinity," by Dr. E. Frankland, F.R.S., at 3 p.m.
Chemical, at 8 p.m.
Royal Soc., at 8.30 p.m.
Linnean, at 8 p.m.
Fri. — *Royal Inst.*, "On Recent Spectrum Discoveries," by Dr. A. W. Miller, at 8 p.m.
London Inst., "On Economic Botany,"' by R. Bentley, Esq., at 7 p.m.
Architectural Assoc., "The Architecture of Napoleon III.," by R. Phenè Spiers, A.I.B.A.
Sat. — *Royal Inst*, "On the Science of Language," by Prof. Max Müller, at 3 p.m.

TO CORRESPONDENTS.

Received. – Madle. T, W. H. P., J. C., G. A. W., Capt. C. P. C., G. H. B., A. and P., T. R. K., W. H. C., W. H. P.

J. C.—Want of space compels us to omit your communication till our next.

G. P. (Manchester.)—No.

Iron.—In a work entitled "A Course of Instruction in Guns and Artillery," by Capt. J. G. Benton, New York, 1862, you will find what you require. You can get it through most "foreign" booksellers. There is a copy in the Patent Office Library, Southampton-buildings The price is about ten shillings.

Ruhmkorff.—You will probably find what you want in De la Rive's "Treatise on Electricity."

I.—We cannot at present definitely answer the first of your questions. As regards the second, we believe that the Iron Plate Committee is still extant. Ships without a wooden backing are now being built, but no ship of this description has yet been fully tried.

John W. (Gosport).—The *gross* amount of income is taken into account, not the *nett* sum. We therefore fear that you must pay the text.

Agricola.—The principal merit of introducing the steam-plough undoubtedly belongs to Mr. John Fowler, of Leeds. We wish him *every* success. Without a patent law, he would stand no chance in getting back the immense sums he has lavished on experiments.

Correspondence.

◆

THE CHIEF CONSTRUCTOR OF THE NAVY.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

SIR,—In your impression of last week you denounce the Armstrong job, and lay bare the manœuvres and motives of its authors in terms which every honest man must approve. The manner in which you have for a long time, single handed, and always consistently, for more than three years, exposed and attacked the gross misrepresentations and partial influences of the leading journal and the Government officials in support of the monster monopoly, does honour to the MECHANICS' MAGAZINE.

All your exertions, however public spirited and high-minded as they doubtless were, have been of no avail to save the country from the expenditure of more than £4,000,000, which have been as much thrown away, at the cost of the oppressed tax-payers, as if the money had been cast into the sea. In spite of your vigilance, the horse was stolen before the stable door was shut. The conspirators planted, and reaped, and gathered the golden harvest at the public expense, with the public eye upon them, and in defiance of public censure. The "Auri sacra fames" was more powerful in high places than patriotism or political honour.

As a measure of public utility the Armstrong scheme has miserably collapsed; as a commercial speculation, which was the sole object of its authors, it is a magnificent success. The partners in the undertaking are enormously enriched. The nation finds itself in the condition of a country which has been overrun and sacked by an invading host, and allowed the enemy to retire unmolested with the spoils of a successful invasion. That catastrophe you would, I am sure, have prevented had it been in your power; and if your attention is awakened to the possible perpetration of another official job, which in its magnitude and disastrous results to the national exchequer and the national defence, if not nipped in the bud, may surpass the "Armstrong iniquity." I make no doubt the MECHANICS' MAGAZINE will signalise itself as much in the new field as it has already done on the great gun question.

The possession of the best ordnance for the land or sea service is an important object, but the possession of the best military navy is one of vastly greater proportions. The gun is a vital part of a man-of-war, but the ship itself, in the aggregate of its construction — its sea-going properties, its strength as a ship, its speed, and, above all, its force of resistance to artillery, is an object involving scientific, mechanical, and structural considerations of the highest order. All the knowledge, all the ability founded on theory and practice, requisite to grapple with these difficult questions, are under the organization of the constructive department required to be concentrated in one man, and that man is the Chief Constructor of the Royal Navy. A late trial, "Clare *versus* the Admiralty," disclosed the fact that the Controller, so far as construction is concerned, is an instrument in the hands of the Chief Constructor. The evidence in that case proved that Sir Baldwin Walker was represented to be the designer of the "Warrior;" but that in fact it is to Mr. Isaac Watts, the Chief Constructor, that the honour of that distinction, whatever it may be worth, is due. How, indeed, is it possible that a naval officer, whose life has been spent in mastering the theory and practice of his own arduous profession, and in attaining its superior grades by slow degrees, should be a naval architect? But the public, uninitiated in such matters, should be undeceived. Things should be called by their right names, and men should be put in their right places. It is no discredit to Admiral Robinson, any more than it was to Sir B. Walker, that he should not be equal to the task of naval construction, or that he should find the chief officer under his *control controls* him. Nor is it to be wondered at that when he conceives he has made the discovery that the officer in whom he has to rely is incapable of exercising a proper control over him, he should seek to place himself under the guidance of a more efficient and a safer adviser. On this principle the recent change at the Admiralty, the retirement of Mr. Watts, and the appointment of Mr. Reed, may be reasonably accounted for. The Controller, we must conclude, has discovered that the former is not up to his work, and we are led by Lord Clarence Paget to infer that he is wanting in the requisite activity. But have the powers of Mr. Watts suddenly failed? Is he not the designer of the "Warrior"—that model frigate, which is held up as the type of iron-clads? I submit these reflections to consideration. They raise the thought that more is meant than meets the eye in this off-hand change in the *personnel* of the constructive department, which, if we may credit a foreshadowing in the *Times*, apparently confirmed by the Secretary of the Admiralty, will be followed up by the removal of other "gentlemen who, although very eminent, are rather old."

But, admitting the soundness of these conclusions two important questions present themselves:—Have we, in the new appointment, got the right man in the right place, or is he an instrument to carry out some cherished plan of the Admiralty, and aid in organizing a gigantic scheme of reconstruction, in which the national wealth and the national interest may be more wasted and compromised than they have been by the Armstrong combination? I confess to grave doubts of that nature, and I will give the reasons why.

Mr. E. J. Reed, whatever may be said of his merits (the *Times* and other papers, including the MECHANICS' MAGAZINE, have not been sparing in their praises of his talents), is an untried man—untried with the exception of the "construction of *one vessel according to his own invention*;" and Lord Clarence Paget informs us "he has done his work extremely well." I pause here to remark that the construction of that *one vessel*, like any other vessel built in the royal dockyards, is the work of the highly trained and thoroughly practical body of shipwrights, masters, and men, who execute the work of any design placed in their hands, in the highest degree of perfection. The credit, then, due to Mr. Reed is simply the design of this vessel of his own invention. That is his title to public confidence. "By his works shall he be judged;" never was an axiom more true than this, as a physical and mental as well as moral test.

With the one exception above mentioned, Mr. Reed's practical experience is a blank. In early youth he studied the theory of naval architecture, and served his time as a draughtsman in the School of Naval Construction. Doubtless, he became a proficient in drawing plans of ships, but there is nothing to show he acquired peculiar eminence, or surpassed his contemporaries in that academy. Whether it was from unwillingness to handle the maul and the adze, or a want of perseverance to pass through the drudgery which is the road to preferment in the public service, he relinquished the opportunity then open to him as a naval constructor, and never has acquired that practical experience which has given to the country a Watts, a Lang, a Turner, a Moody, and other highly trained and talented master shipwrights, who form the real strength of the department of naval construction. In this practical training the new chief constructor is totally deficient. For many years he devoted himself to literary and scientific pursuits, and was only lately brought into notice as the secretary to the Institute of Naval Architects—a situation for which his theoretical knowledge, his natural abilities, urbanity of manner, and high character, well qualified him. The position in which he was then placed brought him into contact with naval men of both parties. By defending the design of the "Warrior" with much success, against its assailants, he ingratiated himself, not only with the Admiralty, but with Sir John Pakington, the president of the institute, who has a parental affection for the magnificent vessel, which was brought into the world when he was First Lord. These circumstances enabled Mr. Reed to bring the design of the vessel of his invention under the notice of the Controller, and led to arrangements which have terminated in his appointment to the important office he holds.

Many months ago, long before Mr. Reed's elevation to the post of Chief Constructor could be thought possible, I pointed out the nature of the system of naval construction, which recommended him to the favour of the Admiralty. That system is known under the designation of "wooden bottoms with iron top sides;" and I stated my belief that in that disguise it was nothing more than a covert plan for resuming the construction of "wooden ships," which, although armour plated, will still be "wooden ships," and nothing else.

I do not propose to offer any remarks on the design, the speed, or sea-going properties of the "Enterprize" or "Favourite." As models of naval architecture and fast cruizers they may be perfection. I have to regard them only as iron-clads. The question lies in a nut-shell. We must have fast corvettes and sloops. Everyone who understands the subject is at one with Mr. Reed on that point. It is no discovery of his. But are these swift cruizers to be built of wood or of iron? Falling into the views of the Admiralty, Mr. Reed would have us believe they must of necessity, at least, for the present, be of wood. For, coming to this conclusion, he assigns two principal reasons:—1, The bottoms of iron ships are liable to foul. 2, The bottoms of wooden ships are stronger and less liable to damage in the shallow waters, where cruizers of light draught are the most serviceable. These two reasons are the sum and substance of the arguments in support of wooden bottoms. Two other reasons adduced are, employment to a large body of shipwrights thrown out of work by iron shipbuilding, and using up the large stock of timber in the dockyards. But this is begging the question. The efficiency of the navy is not to be put in peril on humanitarian grounds, or to relieve the Admiralty of an imprudent investment. If we are to believe half what has been said about the ready conversion of shipwrights into workers in iron, national humanity and national interest may be allied in the construction of an iron fleet; and, instead of wasting the large stock of timber in store by converting it into vessels, which, in a few years, will be obsolete, and laid up to rot in ordinary, it would be far wiser and more economical to sell off this useless—if useless—stock of timber, and apply the large sum it would produce to build iron sloops and corvettes, which will be serviceable for half a century. Such a course would be true economy, and, at this moment, would not only be a great help to the Exchequer, but a national benefit, by adding to the navy a useful class of iron ships without an increase in the budget. This suggestion may be worth consideration, and I trust some independent member will ask for a return of the nature and value of the stock of timber in the Government dockyards.

The real character of the "Enterprize" and "Favourite" may be briefly described. They are literally wooden vessels partially protected with iron armour. To call them anything else is a misnomer, to conceal the truth. From the keel to the gunwale they are of wood. They are built with wooden timbers and wooden planks, and, to form a backing to the armour, the spaces are filled in with wood. The structure is strengthened with iron knees and iron stringers, and great solidity is given to the sides, which are stated to be 18 in. thick, but still they are unequivocally wooden vessels. The iron top sides are independent of the hull, so far as displacement and sea-going strength are concerned. These upper works are rather a source of weakness than of strength, inasmuch that if they were of wood, and were formed to be supported by continuations of the timbers which form the hull, the vessel would be more sea-worthy. These remarks apply only to the ship as a ship, without reference to her qualities as an iron-clad.

The armour plating is divided into, and applied to, two parts. One is termed by the inventor of the system the "belt" armour; the other the "backing" armour. The former commences below the water-line, and continues to the gunwale. The latter protects the battery, which is a square fighting box, similar to that of the "Warrior," occupying the centre of the main deck, armour-plated on each broadside and at the ends athwartship, the width of the deck. There is no invention in this arrangement; it is copied from the "Warrior." As to the arrangement for fighting four guns, either at the broadside or fore and aft ports, I have nothing to say at present, except that four guns cannot be fired from eight ports simultaneously; and the novel expedient of shifting guns from one port to another, in the heat of action, has yet to be tried before its advantage can be determined.

The main consideration is the efficiency of the protective armour. It consists of 4½ in. plates diminishing to 3 in. on a wood backing of 18 in., which, in the case of the belt, is the hull of the ship itself. It has been asserted, that with this system of armour, the vessel is as completely protected as the "Warrior;" but that is a misrepresentation, because in addition to 18 in. of teak backing, the "Warrior" is protected by her iron skin and framing, which, together, offer greater resistance to projectiles than the 18 in. of wood. The iron-cased belt of the "Enterprise" is of the same strength only as the armour plates and teak backing of the "Warrior," and is, therefore, far from being as completely protected. Wanting the support of an iron hull at the back of the 18 in. of wood, the planks and timbers of the "Enterprise" will be crushed in or splintered by the impact of 7 and 8 in. solid shot, even though the plates should not be perforated. The certainty of that result is demonstrated by the effect produced on the planks and timbers of wooden ships in testing armour plates at Portsmouth. As to shell, the late trials at Shoeburyness leave no doubt that explosive projectiles will pierce through the 4½-inch armour, and set a wooden ship in flames. In an engagement with a completely protected and heavily-armed *iron* iron-cased ship, the "Enterprise" would, at close quarters, be destroyed, or strike her colours in a few minutes.

Such is the class of ships, which it appears to be the special mission of the new Chief Constructor to aid the Controller to introduce into the navy. It is, under the circumstances described, impossible to disconnect the scheme and its author, whose sudden promotion over the heads of his more experienced and practical seniors, interpreted as it is by the articles in the *Times*, strongly eulogistic of the coming man and his system of wooden iron-clads, leave little doubt, in my mind, of the intention of the Admiralty. There will be, we are led to expect, sweeping reforms in the department of naval design and construction. The new-born Chief, we are assured, combines in his person "special qualifications for his post, resulting from the highest training in the theory and *practice* of ship building;" and the first duty imposed upon him is to remove from office his present subordinates, who, it is insinuated, are "effete nullities," and ought to be replaced by "more highly-educated assistants taken from the training school of mathematics and naval construction."

These reflections on the *personnel* of the Controller's Department are anything but complimentary to the persons of whom it is composed. Similar opinions have been before expressed; but it is by no means certain that any change of persons, under the present "system," will bring about that reform in Whitehall which is so urgently required. If the occupants of office are *effete*, it is because the system itself is essentially so, and it would be as rational to attempt to restore old age to youth by transfusion, as to change the character of Admiralty administration by substitution of persons, who, whatever may be their ability, can only be instruments of a corrupt, a torpid, and a cumbrous department. If the panegyrics on the new "Chief Constructor," are well bestowed, Mr. Reed might be hailed as the "Young Napoleon" of the Admiralty. Time will show whether it is possible for genius to surmount the dead weight of a vicious administration, any more in Whitehall than in Washington.

Under a constitutional *regime* we must not rely upon mere personal talent or influences. The most scrupulous conservative may prefer a change of "system," and rally to the cry of "measures not men," because good measures must be founded on a good system, which will put the right men in the right places.

The development of the Reed scheme should be closely watched. It cannot be allowed that the Chief Constructor, as it has been asserted, comes into place free from "bias" in favour of wood or iron, as the material for naval construction. Much less can it be said that he is not an inventor. Is it not notorious, and is it not announced by the Secretary to the Admiralty, that he is the inventor of "wooden bottoms with iron top sides," of which he claims to be the original designer? His alleged "immunity from bias" may be likened to that of the patient animal between two bundles of hay, or to the Macheath sentiment, "How happy could I be with either," for Mr. Reed by turns has been the staunch advocate of iron ships, and the derider of the "men of iron at any price." He has staked his reputation on the hermaphrodite class of cruisers, which are neither wood nor iron, but a mysterious combination of both. As to his practical knowledge, it has been shown what it is.

The origin and progress of the relations between Mr. Reed and the Controller's Department, strengthen the impression that the composite ship may be a contrivance to enable the Admiralty to resume the construction of a wooden navy. The prominence suddenly given to the author of the plan, and the exalted patronage bestowed upon him, favour the suggestion that such a design is intended to be carried out in opposition to the recorded will of the House of Commons, that no more wooden ships shall be built.

The contest between wood and iron is culminating. My predilections are decidedly in favour of iron. I may be accused of having a "bias," but the occasion of arriving at a right conclusion is at hand. The navy estimates are brought forward. Should a vote be proposed for the construction of a fleet of "wooden bottoms," it may be concluded that Mr. Reed's mission is to uphold wood against iron. In that event, I trust you, Sir, will cordially give your support to a proposal that Government shall be required to make a trial of a wooden iron-clad target constructed on the Reed plan, before the construction of another "Enterprise" or "Favourite" be commenced.

The House of Commons, if it does its duty, must interpose and prevent a repetition of the monstrous folly of building a fleet of iron-clads on a plan not previously tested. The trial of the "Warrior" system of armour-plating was not made at Shoeburyness until after that vessel was built and ready for sea, and eight or ten other ships, to be protected in the same way, were under construction. Whatever may be the merits of the "Warrior" plan, a better one is allowed to be a desideratum. The Reed plan will unquestionably be vastly inferior in efficiency. A target trial will settle the point, and may prove it to be worthless. This trial ought to be made! The country is to be relieved from the incubus of the Elswick Ordnance Company; at an enormous sacrifice, it is true, but this sacrifice may have its utility. It may rouse the Legislature to step in at the opportune moment, and, by insisting upon a trial of the Reed system, it may avert the possible danger of a waste of the public money on a scale more prodigal than that resulting from "Armstrong diplomacy."

I am, &c.,

CIVILIAN.

CUPOLA SHIPS.

SIR,—In the discussion last night on the naval estimates, Lord Clarence Paget, having stated that cupola ships would be under a disadvantage when fighting both sides, will you kindly allow me space for the following facts, viz.:—

"Defence" throws a broadside of 560 pounds, and is 3,720 tons. The "Prince Albert" shield ship throws a broadside of 1,120 pounds, and is 2,529 tons, and has the power of fighting half her guns on either sides, giving her then a broadside of 560 pounds, or equal to the "Defence," although the "Prince Albert" is 1,600 tons smaller.

I am, &c.,

COWPER P. COLES.

London, Feb. 24.

SUBMARINE TELEGRAPHY.

SIR,—Judging from the harmless nature of the fire returned by "An Old Sailor" in your last issue, I am sadly afraid I hit him harder than I intended—in short, that my shot struck him below the water-line and crippled him outright. He throws out a hint, however, of which I avail myself, by closing my correspondence with him at this point.

"An Old Sailor" says:—"If Dr. Wallich considered my observations worth answering at all he should have replied with temper." Why, the fact is, my missiles were too well tempered—they were steel-headed, otherwise it is difficult to conceive how "An Old Sailor" could have penned such a chaotic sentence as the following:—"Whether a writer in your paper announces his name or writes anonymously, I apprehend that so long as he writes common sense, and his arguments on the subject are sound, it matters little to your readers."

Having failed to detect the "common sense," or "sound argument," which "An Old Sailor" declares he has "written," I beg leave to assure him I shall neither trespass on your space nor your readers' good nature, by attempting to refute assertions which, I repeat, are unsupported and irresponsibly made.

When "An Old Sailor" shall have perfected his scheme of "a voyage to the moon," which he tells us he "may propose," perhaps he and the public may unanimously agree in its being a fitting opportunity to break his *incognito*.

I am, &c.

G. C. WALLICH.

Kensington, Feb. 23, 1863.

[We do not see the necessity of sneering at an "An Old Sailor," because he does not reveal his name. Almost all journalism in this country is anonymous. It may not be always convenient or politic for a writer to sign his name; and we beg to inform Dr. Wallich that "An Old Sailor" is quite competent both from experience and position to write on this subject.—ED. *M. M.*]

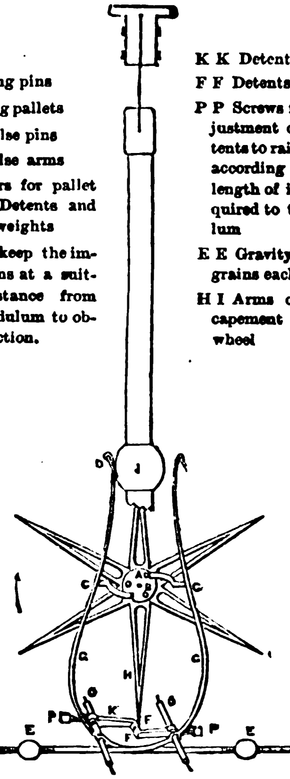
ON GRAVITY ESCAPEMENTS FOR CLOCKS.

SIR,—The interest I have for many years taken in the progress of horological science, and in carrying into practical effect various designs with the view of improving and simplifing the principles of time-keepers, induces my offering for publication in your valuable journal the following observations as the result of my own experience in reference to gravity escapements for astronomical clocks and turret clocks of large dimensions. I might not have troubled you, at the present moment, had not an article on the subject of gravity escapements, by Mr. E. B. Denison, appeared in the MECHANICS' MAGAZINE for February 13th, 1863, justifying a few observations on my part, in which, for the purpose of distinction, I may mention names as referring to inventions only, but without any controversial intent or bias on either hand.

In my remarks here it will be not necessary to say anything on the general construction or purpose of gravity escapements, after the description given by Mr. Denison, illustrated by five diagrams in the above mentioned paper, and in his rudimental treatise on clocks, both which may be referred to; he, however, after describing clocks of his own construction, speaks of other clocks in the International Exhibition somewhat disparagingly, without having, as it appears to me, sufficiently investigated some points of real importance distinguishing one particular clock, to enable him to report fairly on its merits, as evidenced by statements in his paper diametrically opposed to the manifest properties of the clock so criticised; and in every instance without mentioning the names of the respective exhibitors of other clocks as a guide to the reader.

To observers familiar with the various specimens, the intention of Mr. Denison, in the several comments, will be sufficiently obvious.

As touching the priority of invention relating to gravity escapements having a scape wheel with a few long teeth for locking, and a few very short ones or pins near the centre for lifting the pallet (and to which in an early model of my own construction I had employed a fly, carried by an extra pinion), but did not apply one to the clock I am about to describe, as it performed well in its simple condition, and would only *trip* when an *excess* of force was applied to the strain.



A B Lifting pins

C C Lifting pallets

D D Impulse pins

G G Impulse arms

O O Arbors for pallet arms. Detents and gravity weights

J Boss to keep the impulse pins at a suitable distance from the pendulum to obviate friction.

K K Detent arms

F F Detents or stops

P P Screws for the adjustment of the Detents to raise or lower according to the length of impulse required to the pendulum

E E Gravity weights 5 grains each

H I Arms of the escapement or star-wheel

Mr. Denison says, "Of the classes of escapements or clocks, with and without the fly, the latter class is represented by Mr. Bloxam's, and the former, I believe it has never been denied, are mine." To this remark I am justified in replying, that a clock in action, having a gravity escapement originally constructed by me of a corresponding principle with that of Mr. Denison, but without a fly, was, for some months, publicly exhibited, A.D. 1843, in the open window of a shop occupied as my place of business, in Piccadilly, just 20 years ago, the other clock being made about three years earlier. In evidence of this, I have the testimony of competent judges, who at the time fully understood the construction and properties of both clocks. I had never, myself, heard of Mr. Denison's escapement until several years later.

Under those circumstances, I think I may fairly claim the originality of this invention, priority on my part being dependent on the later exposition or publication of Mr. Denison's escapement for the Westminster great clock, as appears by the date 1852, given for the first application of a fly to his three-legged gravity escapement.

The above conclusion is drawn from a recent inspection of the great clock in the tower, where I had full opportunity of comparing Mr. Denison's gravity principle with my own.

The particular clock unfavourably commented on, cannot, from the points of principle objected to, be mistaken as to the gravity escapement invented by Dr. Clark. One important property of his principle is its unlocking by the descent of each gravity impulse, weight, and pallet, the invented impulse arm of which acts continuously on the pendulum, until the unlocking of the star wheel is effected. Upon this reversed mode of unlocking by the falling pallet, Mr. Denison says you will have the friction on the stops acting, not merely through a very short arc, and in one direction only, "but first forwards and then backwards through the whole swing of the pendulum, both up and down; in fact, exactly corresponding to the dead friction in a dead escapement."

Both points in the latter portion of the above statement, I find, by an acting model in my own possession, to be entirely a mistake, as in the upward motion of the locking pallet by action of the lifting pins; there is no contact either with the pendulum or with the tooth of repose, which passing gradually away from one pallet until the next tooth is arrested by the other pallet, sufficiently explains the correctness of Dr. Clark's mode of infallible locking, which allows any increase of motive power, without the possibility of tripping, and under a proper direction of the locking planes the arc of vibration will be constant, the quantity and intensity of friction being about 100 times less than in a dead escapement. No oil is required except at the detent pivots, as guarding against rust; this and other advantages stand favourably for the permanent well-going of a clock with this gravity escapement, which, if properly made, would, I believe, be found satisfactory.

I may here express an opinion that, giving impulse on the pendulum rod by inverted impulse arms, induces too small an amount of friction to admit of valid objection, the intersection of the curves at the line of centres for so small an arc of motion being barely appreciable. It is so much less than the detent pivot friction produced by the weight of parts, as to be too fractional for consideration.

The lettered engraving fully illustrates Dr. Clark's arrangement, both lockings being in the vertical line of the pendulum rod; the momentum of the star wheel allows a little re-action of the second hand, but this is completely remedied by a simple check, as in the model before mentioned.

I am, &c.,
JAMES F. COLE.

5, Queen-square, Bloomsbury,
Feb. 24th, 1863.

SILICATE OF POTASH.

SIR,—I observed in your number of January 2nd a correspondent asking how to make silicate of potash, soluble in boiling water. He says he took 15 parts of quartz sand, and 10 parts of carbonate of potash, and 4 parts of charcoal in powder. Let him take 15 parts of carbonate of potash, and 6 or 10 parts of sand, bearing in mind that the less sand the more soluble will be the compound.

I am, &c.,
G. C. P.

Gossip.

A new system practised in armour-plating the ships of the French navy has been introduced, which it is expected will have the effect of warding off the dry rot, and preventing decay. It is effected by carbonizing with a flame of gas the surface of the timber before receiving the plates. In order to obtain a satisfactory test of the effect of this system, an equal number of the plates has been laid on without the carbonizing, and the system will be applied to the remainder of the strakes to obtain the necessary result.

On Saturday last a very magnificent screw steamer was launched from Messrs. C. and W. Earle and Company's shipbuilding yard, at the Victoria Dock, Hull. At the moment of taking the water the vessel was named the "Lotus." She is intended for the Mediterranean trade, and is owned by Messrs. J. Moss and Company, Liverpool. The registered tonnage of the "Lotus" is 500 tons; her actual burden, however, will be about 800 tons, and her dimensions are: length over all, 220 ft.; breadth, 21 ft.; and depth, 15 ft. 2 in. The launch was a very successful one, and the vessel presented a very graceful appearance on the water. Messrs. Earle and Co. have two other large steamers on the stocks, and two others will be laid down shortly. Messrs. Martin Samuelson, iron shipbuilders, are also doing a considerable trade. They have at present four large vessels in course of construction, and others will be laid down as soon as these are turned out.

His Royal Highness the Prince of Wales has intimated, through General Knollys, "his great pleasure in becoming the Vice-Patron of the Royal National Lifeboat Institution; and in contributing a donation of £30 for the purposes of the institution."

A company has been formed for the purchase of Messrs. Perrin and Delmas' patent (adapted to revolvers and cartridges) for which the prize medal of the International Exhibition, 1862, was awarded; and also for the manufacturing of modern improvements in firearms, and the adaptation of the patent to carbines and rifles. Prospectuses, and forms of application for shares, may be obtained at the temporary offices of the company, No. 3, Sun-court, Cornhill, and of the brokers.

Nine spots of different forms and sizes are now to be seen on the sun's disc.

The "Montauk," one of the "Monitor" ironclads, was lately in action, near Savannah, and used her 15-inch guns for some time. The Confederate work, however, was so massive that not even these tremendous projectiles were able to damage it. The range was long—600 yards. The "Montauk" was struck repeatedly by heavy shot from the rebel guns, but was not injured or caused to desist in her attack by them.

Messrs. Palmer Brothers, of Jarrow, have no less than 20,000 tons of iron shipping on hand. One of these vessels, a screw steamer of 2,686 tons burden, will be launched in a fortnight; the others are in various stages of progress. The ship nearly ready for launching is the "Georgia." She is one of ten which Messrs. Palmer are commissioned to build for Messrs. Fernie Brothers, of Liverpool, and which are meant to bring cotton from New Orleans. Another clipper ship of 1,100 tons is being built for Australia; and other four are for the Mediterranean; one of them will be 1,500 tons, and the others 900 tons each. Three of these are for a London firm, and one for a house in Genoa. A screw steamship of 2,000 tons is building for Messrs. Wilson, Chambers, and Co., Liverpool, and will form one of the White Star fleet trading to Australia. The other vessels are principally building for the coasting trade.

DRILL YOUR CENTRES.—If machinists, and others in the habit of using engine lathes, says a contemporary, only knew how much time and trouble are saved by the simple practice of drilling a centre, they would never omit it when about to turn a shaft. In the first place, to make a centre with a centre punch is to be guilty of a very unmechanical proceeding; the centre in work to be turned should be round and true; it ought also to conform to the shape of the dead or live centre of the tool which it is to be turned in. This feature cannot be obtained with a centre punch. The latter are always ground up to a sharp point on a stone, and are more apt to be triangular, than cylindrical in shape. Notwithstanding all these bad features, the punch is employed with the utmost confidence by a great many mechanics—by far too many—as a substitute for the drill. "It takes too long to drill the centre," says Shiftless, and then whack goes the hammer, and a three-sided conical kind of a cavity is indented into the shaft, and the clumsy workman proceeds to turn it down. In all probability he does not get two inches in length on it, before the work comes leaping out of the lathe and lies in the bed a faithful witness of his want of skill and forethought; the result is that the centre has to be renewed and the shaft runs out of truth. Now how much better it would have been to have drilled the shaft at once, and so made a perfect job—one that would last. Very often work goes out of the machine-shop and comes back again to be done over, because the person for whom it was made did not know what he wanted; or for other reasons, then the utility of a drilled centre is fully apparent, as the shaft may be put in the lathe and it will run true, whereas in a centre made with a punch there is no reliance of any kind to be placed. Again we say, then, drill your centres!

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

THE Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

STEAM ENGINES, &c., 2139, 2145, 2159.
BOILERS AND FURNACES—*none.*
ROADS AND VEHICLES, including railway plant and carriages, saddlery and harness, &c., 2141, 2156, 2158
SHIPS AND BOATS, including their fittings, 2128, 2129.
CULTIVATION OF THE SOIL, including agricultural implements and machines, 2160.
FOOD AND BEVERAGES, including apparatus for preparing food for men and animals, 2134, 2138.
FIBROUS FABRICS, including machinery for treating fibres, pulp, paper, &c., 2137, 2142, 2155, 2162, 2163.
BUILDINGS AND BUILDING MATERIALS, 2157, 2164.
LIGHTING, HEATING, AND VENTILATING, 2127, 2133, 2140, 2143, 2148, 2150, 2154, 2165, 2170.
FURNITURE AND APPAREL, including household utensils, time-keepers, jewellery, musical instruments, &c., 2144, 2147, 2151, 2161. 2167, 2168.
METALS, including apparatus for their manufacture, 2166, 2171.
CHEMISTRY AND PHOTOGRAPHY, 2130, 2132, 2133.
ELECTRICAL APPARATUS, 2131, 2153.
WARFARE, 2149.
LETTER-PRESS PRINTING, 2152.
MISCELLANEOUS, 2125, 2135, 2146, 2169.

2126. R. LOW and W. DUFF. *Improvements in apparatus or means for producing an adjustable pressure on certain parts of machinery.* Dated July 26, 1862.

This refers to the pressing rollers of machinery for spinning flax. A knee piece is attached to or cast in one with the grate or serrated bar, which extends over the wooden rollers in front of the drawing rollers. This knee piece is curved in a downward direction, and terminates in an eye which is screwed internally. To this eye is fitted a tube, screwed externally to correspond to the eye, and terminating at one extremity in a hand wheel or cross head, by which the tube may be screwed more or less through the eye. Inside the tube is placed a series of discs, or a piece of india-rubber, in front of which is fitted a metal plug which slides to and fro in the tube. The end of this plug extends out beyond the containing tube, its extremity being hollowed so as to fit the arbor or spindle of the contiguous wood roller. By screwing the tube into the eye, the end of the sliding plug piece may be caused to bear with any required degree of pressure on the wood roller, and as this roller drives the drawing roller by frictional contact therewith, the pressure of the one is imparted to the other. In this way any required degree of pressure may be obtained with great ease and certainty, at the same time dispensing with the use of levers, weights, and other complicated details. *Patent completed.*

2127. J. WALTON and J. MOORE. *Improvements in the mode of ventilating and heating rooms, Turkish baths, hothouses, and buildings of all kinds.* Dated July 28, 1862.

This invention consists of two parts, which may be used separately or together, for ventilating and heating rooms, carriages, huts, and buildings of all kinds. When required to heat buildings, the patentees generally combine the heating arrangements with the arrangements for ventilation. The apparatus for carrying off vitiated air from a room or other building is placed at the ceiling or upper part of the room or building, and is composed of a conical tube, the larger and lower end of which opens into the room, and the smaller end either opens directly into the outer atmosphere, or communicates with it by a pipe. Through this conical tube the vitiated air escapes from the room or building. Around the conical pipe is a cylindrical pipe of larger diameter than the bottom of the conical pipe, so that there is an annular space between the bottom of the conical pipe and the bottom of the cylindrical pipe. The upper end of the cylindrical pipe also communicates with the outer atmosphere, and as vitiated air passes away from the room through the conical pipe, fresh air enters the room through the space between the bottom of the conical pipe and the bottom of the cylindrical pipe. In order to supply a room, Turkish bath, or other building with heated air, the following arrangement is employed:—Above a fireplace or furnace is formed an air chamber, the bottom of which is heated by the fire, and is formed of fire bricks or tiles—by preference, the fire-bricks made of pipe clay. Air is admitted into this chamber from other chambers formed at the sides of the fireplace or furnace, air being admitted into the front of those chambers from the outer atmosphere; the heated air passes away from the back of the chamber above the fireplace through a passage or flue, which conducts it into the Turkish bath, or into the room or building to be heated, the passage or flue being, by preference, conducted beneath the floor of the bath or building, and openings or gratings are formed in the top of the flue to permit the heated air to enter the bath or building. Beneath this hot air flue is conducted the smoke flue of the fireplace or furnace, so that the air in the air flue is kept heated by the smoke flue, and the top of the smoke flue, which also forms the bottom of the hot air flue, is, by preference, formed of the fire-brick or tile above mentioned. A large body of air will thus be heated and allowed to enter the room or building, but no portion of the air will at any time be so highly heated as to partially burn or decompose it, and thus render it injurious to animal life. *Patent completed.*

2128. H. Bollinger. *Improvements in machines employed in ship building, parts of which are also applicable to other purposes.* Dated July 28, 1862.

This invention consists, first, in an improved cutting machine for cutting off the ends of angle iron or other shaped bars, but chiefly intended for cutting off the curved ends of ships' frames. Secondly, in an improved blowing machine for working blast and other furnaces. Thirdly, in improvements in rivetting machines for rivetting the beams and ribs of ships, and other parts which can be rivetted up before putting them in their places, and also for rivetting marine and other boilers, bridges, and metal girders. Fourthly, in an improved universal slotting and drilling machine, either portable or stationary. And fifthly, in an improved double acting shaping machine, with revolving cutters to be used in constructing vessels, and also the machines before mentioned. *Patent completed.*

2129. C. W. Eddy. *Impeding a channel against the entrance of ships and vessels, and in particular of screw ships.* Dated July 28, 1862.

In carrying out this invention, the inventor constructs several nets of rope, and in particular some of coir or Manilla rope, or of other light material, which will float horizontally on, or a little below, the surface of the water, without the aid of buoys, or at least with but little aid from them. He places these nets across or partially across the channel to be impeded, where they may be secured by anchors or other fastenings. And he proposes that, when the nets are required to be of considerable length, they may be manufactured in squares, which may be towed separately to their proper positions, and there laced together, the whole thus forming one net or system of network. *Patent abandoned.*

2130. W. Spence. *Improvements in the preparation of a red colouring matter.* (A communication.) Dated July 28, 1862.

This invention has for its object, in the first place, the transformation of phenic or carbolic acid into a red colouring matter. Secondly, the transformation of this matter into a fast colouring matter, capable of resisting the action of acids and other agents. And thirdly, the application of this substance to dyeing and printing. The colouring matter is first prepared thus:—The inventor takes about 23 lbs. of phenic or carbolic acid, from about 10 to 20 lbs. of oxalic acid, and from about 7 to 14 lbs. of sulphuric acid. This mixture is heated until the colouring matter is formed of the requisite colour and consistence. When this operation is considered to be finished, the matter is washed with boiling water, in order to remove the excess of acid. It is then in the state of a light pitch, and with a green shade of cantharide. It may be dried and reduced to powder by means of heat, or by a longer process without heat. The matter thus produced is converted into more solid matter by the following process:—The inventor takes about 2¼ lbs. of this less solid matter, and about 5½ lbs. of ammonia of commerce. This mixture is put into a closed metallic vessel, then heated to a temperature of about 270 deg. Fahr. for about three hours. This is allowed to cool, and then the vessel is opened. The matter originally introduced therein becomes completely dissolved in the ammonia, thence yielding a liquor rather thick, and possessed of a considerable colouring matter. This liquor when heated by acids furnishes a deep red precipitate, which is the fast colouring matter modified as required, and which is capable of dyeing red silk, wool, and other textile materials. The matter thus prepared is called "peonine," and is applicable to dyeing and printing generally. *Patent completed.*

2131. P. S. Devlan. *Certain improvements in the manufacture of telegraphic cables.* Dated July 28, 1862.

The cable constructed according to this invention consists of a number of insulated wires, collected and arranged together to form the cable, and is designed for the purposes of flexibility, durability, tenacity, and strength. The improvement consists in coating the wires to be insulated with a composition consisting of about 8 lbs. of paper, or other fibrous pulp, half a pound of caoutchouc or gutta percha, with 1 lb. of resin, or thereabouts. The composition is thus applied. The inventor takes one or more of the ordinary conducting wires, over which he puts a complete coating of the composition in any required thickness; this coating of the composition is put on while the latter is in a soft condition, and may be applied by suitable dies or drawing machines for the purpose. When the coating has become sufficiently dry, he braids or plaits over it a coating of fine strong cord; over this covering of cord he applies another coating of the composition, and over it another cord covering, and so on until the cable is completed. *Patent abandoned.*

2132. W. Spence. *Improvements in the preparation of a blue colouring matter.* (A communication.) Dated July 28, 1862.

For the purposes of this invention, there are taken about five parts of the matter which has been called "peonine" in the specification of a patent granted to the present patentee as a communication from abroad (No. 2130) in the year 1862, and described therein as a red colouring matter prepared from phenic or carbolic acid, and from about 6 to 8 parts of aniline. The mixture is heated to a temperature near to the boiling point, which heating is maintained for some hours, until the material is completely transformed. The result hence obtained is a blue colouring matter, which is purified by successive washings; first, with boiling water acidulated with sulphuric, hydrochloric, or other acids; secondly, with heated coil oil; and thirdly, with a dilute solution of caustic, soda, or potash, or other alkalies. The matter thus obtained is passed into acidulated boiling water, then dried. It is then in a state of powder, with golden shades soluble in alcohol, methyle, and other spirits, and the solutions of which may be used directly for dyeing and printing. The colouring matter thus obtained is called azuline, and is applicable to dyeing and printing generally. *Patent completed.*

2133. P. A. Favrichon. *An apparatus for the speedy and economical heating of baking ovens, and also for using the excess of heat, which is called "Oven of Valfort and Favrichon, Bros."* Dated July 28, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2134. W. Maugham. *Improvements in the manufacture of effervescent beverages.* Dated July 28, 1862.

In accordance with this invention, the patentee dissolves phosphate of soda, preferring that commonly called phosphate or rhombic phosphate of soda, at the rate of six drams troy to half a pint of water; and to render this liquor aerated it is only necessary to pass it into a sufficiently strong and properly closed vessel, and then to charge it with carbonic acid gas, under a sufficient degree of pressure, which may be varied so as to be greater or less, at the will of the manufacturer. *Patent completed.*

2135. T. Cooke. *Improvements in apparatus employed in the manufacture of envelopes.* Dated July 28, 1862.

For the purposes of this invention a sliding table is used, carrying two die boxes, and the sliding table is arranged and worked in such manner as to be moved to and fro upon a stationary table, in order to bring the two die boxes alternately under a plunger. The plunger descends twice into each die box; at the first descent it creases the envelope paper by pressing it into the die box, and at the second it folds in the flaps. After the paper has been creased the flaps are folded inwards by means of levers or instruments working inside the plunger. When the plunger is at the top of the stroke the levers project below the plunger, and extend beyond its sides, so that, in the second descent of the plunger, they catch the ends of the flaps of the envelope paper, which are projecting above the die box, and carry them inwards under the plunger, which then completes the folding of the envelope. After the plunger has risen for the second time the sliding table is moved a distance equal to that required to bring the other die box (covered by a piece of envelope paper) under the plunger. This movement of the sliding table also brings the die box in which an envelope has just been completed into a position beyond the stationary table, which enables it to discharge such envelope into a proper receiver. A fresh piece of envelope paper is then placed over this die box, which will in turn be carried by the die box under the plunger, when the sliding table is again moved. By these means envelope paper will be folded in the die boxes when they are alternately brought under the plunger. *Patent completed.*

2136. A. Noble. *Improvements in obtaining and treating compounds of alumina.* Dated July 28, 1862.

One portion of this invention is carried out as follows:—In order to obtain a preparation of alumina, which, for many purposes, may be used as a substitute for alum, the patentee takes clay, or material containing variable quantities of alumina oxide of iron and water, and treats it with hydro-chloric acid in the following manner:—He takes the clay, or other material, and after having ground it to a fine powder, and calcined it in a reverberatory furnace at a low red heat, he exposes it to the action of hydro-chloric acid gas, which is taken as it comes from the furnaces in the ordinary plan of making salt cake; or it may be obtained in any other convenient way, care being taken that the temperature of the gas is somewhere above 200 deg. Fahr. If the temperature is too high, no action will take place, and, if too low, the compound will become partly liquified. When the operation has been successfully performed, the resulting substance, which he calls crude chlor alum, is in a dry state; it consists of a mixture of chloride of aluminum, with some chloride of iron, silica, water, and other substances. The apparatus the patentee finds suitable for carrying on this operation consists of a chamber built of sandstone, fire brick, or other material little acted on by hydrochloric acid, and furnished with shelves of the same material, arranged in such a manner that the current of hydrochloric acid gas shall circulate over each. The prepared clay is thinly spread (say, in layers from 1 to 2 in. in thickness) on these shelves. A good plan is to place the chamber in such a position that the hydrochloric acid gas can pass through the chamber on its passage from salt cake furnaces to the usual condensing powers, so that all the hydrochloric acid gas not absorbed by the clay passes on to the tower, and it is condensed in the usual way. *Patent completed.*

2137. J. Fourdrinier. *Improvements in apparatus for removing knots from pulp.* Dated July 28, 1862.

For the purposes of this invention an upright cylinder is used, the periphery or circumference of which is formed with numerous upright slits of the form and character of those used in other knotting apparatus. This cylinder is placed within another cylinder, or vat, from which the pulp is conveyed to a paper-making machine. Within the first-mentioned, or inner cylinder, a rotating apparatus is applied, in order that the pulp, which is continually fed into the interior of the cover, may be continually dashed, thrown, or projected against the inner surface of the cylinder, and thus caused to pass through the slits, or openings, formed thereon into the outer cylinder, or vat, whilst the knots are retained within the inner cylinder. *Patent abandoned.*

2138. J. Ellis. *Improvements in apparatus for washing corn and other grain.* Dated July 28, 1862.

This invention consists of machinery, or apparatus, arranged and working as hereinafter described. Overhead is a feed hopper, with a regulator at bottom, to make the outlet larger or smaller, as may be desired. The grain falls from this hopper into a chamber with an inclined perforated bottom, where it is stirred by agitators on a revolving shaft, and worked down the incline into a perforated inclined cylinder, where it is acted upon by brushes on a revolving shaft. The grain is worked to the lower end of the inclined cylinder, and falls into a receiver, from whence it is elevated by an endless chain carrying buckets, and discharged from the buckets into any desired receiver. Under the inclined chamber and cylinder are V shaped troughs, fitted with valves, or taps, at bottom, opening into an inclined channel common to all the troughs, from which the dirt separated and washed out from the grain is run off. There is also a valve fitted to the further end of the chamber, into which the grain falls from the inclined cylinder. Steam, hand, or other power, may be used to drive the apparatus. *Patent abandoned.*

2139. F. Selby. *Improvements in surface condensers.* Dated July 28, 1862.

This invention was described and illustrated at page 89 of the present volume of this journal. *Patent completed.*

2140. H. Hedgeley. *Improvements in lamps.* Dated July 28, 1862.

The first part of this invention relates to lamps known as moderators, and consists of certain improvements in the means of overflow of the oil, by the adoption of which moderator lamps may be made to burn paraffin or other mineral oil without any exposure of the oil. The patentee forms a burner of a particular shape, consisting of two and three tubes, the inner tube to hold the wick; the second tube to form a case and overflow; the outer or third tube to cover all in, and prevent evaporation or effluvium from the oil in its flow, And in order to obtain perfect combustion, he uses, in lieu of a cone, an oxydation glass or chimney, of a certain shape (as shown in the drawing). He forms slots or apertures on each side of the wick holder; or in lieu thereof a series of small openings at any desired distance below the top. Through these apertures the excess of air will flow, instead of continuing its upward course to the top of the wick tube. Or in lieu thereof, he uses a short overflow tube, and places a fixed cap thereon to form the requisite continuation of the burner. The oil will thus flow down the exterior of the holder, and within an outer casing or cylinder, which is to be screwed or fixed around the holder. This outer casing is to be fitted so as to exclude the air, and thus to completely confine the oil and prevent its evaporation. The oil will pass through suitable orifices down either one or two tubes into the reservoir of the lamp, and may be again pumped upwards. The patentee effects improvements in plungers of moderator lamps, in order to render them more effective in maintaining mineral oils below the said plungers, by making the plunges of metal nearly the diameter of the cylinder, the centre thereof being raised into a dome, and by attaching a ring of leather, the lower part of which ring expands and fills up the intervening space between the plunger and cylinder. The second part of the invention refers to lamps or chandeliers where the oil is contained above or at the level of the light. He causes the oil to flow from the said reservoir through arms or pipes to the burner, which burner is above the overflow. The tubes are made in the same way as in the former instance, the rack spring and plunger being dispensed with, as the oil ascends by hydrostatic pressure to a certain level, and then by capillary attraction. *Patent completed.*

2141. E. Burnet. *An improved combined cart and sleigh.* Dated July 28, 1862.

This invention consists of a novel construction of vehicle forming a combined cart sleigh. The shafts are jointed by a hinge to the cart or sleigh, and at a short distance from the joints underneath each shaft a curved branch or arm of iron descends, forming a connecting stay, which is attached to a flat spring extending across the under part of the boot, to which it is attached by bolts, screws, or other fastening. The curved arms are hinged at a short distance from their attachment to the shafts, in order to allow the shaft points to descend to the ground when the cart is not in use, and also to prevent fracture or other damage to the shafts or cart in the event of the horse falling. This arrangement also relieves the shafts of much weight and strain. The springs are formed of elliptical bars or plates, and only consist of four plates presenting the appearance of a small spring inside a larger one, with which it is only connected at the upper and lower bearing surfaces of the cart and axle. The seats are made to hold four persons who sit back to back: the front seat is adjustable, and can be shifted backwards when only two persons are to ride, so as to cause the cart to balance as when four persons are riding. When the wheels are removed, as well as the iron feet on which the cart falls forward and bears on the ground when not in use, the body can be attached to a sleigh frame, and be used in winter as a sleigh with all the advantages of the spring shafts before described. *Patent completed.*

2142. J. L. Jullion. *An improvement in antichloride for paper working.* Dated July 28, 1862.

Provisional protection has not been allowed for this invention.

2143. C. W. Siemens. *Improvements in gas engines.* Dated July 28, 1862.

This invention has reference to that class of engines in which motive power is obtained by the expansive action resulting from the combustion of a mixture of an inflammable gas, or of inflammable gases or vapours, and atmospheric air within a closed chamber or cylinder. One part of the invention consists in certain improved means of igniting the mixed gases and atmospheric air as they enter the combustion chamber or cylinder. Another part of the invention has reference to the mode of admitting the combustible gases and air into the working cylinder, and of discharging the products of combustion therefrom after expansion. Another part of the invention consists in certain improved means for preventing the destruction of the reservoir through an accidental explosion of the combustible gas and air, when these are contained therein in the form of an explosive mixture. *Patent abandoned.*

2144. R. Thompson. *A new and useful improvement in lock stitch sewing machines.* Dated July 28, 1862.

This consists, 1. In making the packing-box in which the hook revolves of raw hide, cloth, felt. 2. In constructing the moveable bobbin case with a start upon its outer end, for revolving the said case with the hook, and also to act as a cast-off for the thread when the point of the hook has entered the loop formed by the needle. 3. In making the body of the start elastic, and so attaching it to the bobbin case as to spring out a little from it, in order that the said case when placed in the hook may be prevented from working out by the friction of the elastic start. 4. In the use of a spring on one side of the hole in the hook, and a screw passing from the outside of the hook against the said spring, whereby the tension of the bobbin thread can be regulated without the removal of the bobbin or its case. *Patent completed.*

2145. Z. Colburn. *Improvements in steam engines.* Dated July 29, 1862.

We cannot here devote space to the details of this invention. *Patent completed.*

2146. J. Mackenzie. *Improvements in shaping machines for curvilinear surfaces.* Dated July 29, 1862.

This machine has the ordinary frame used for planing and shaping machines. The cutters are fixed on the cutter block in the usual manner; the latter—that is the cutter block—is mounted upon an axle or spindle, either by being keyed to it, or forged with it, which is driven by bevel gearing. This bevel gearing is in this case of great importance, as it allows of the spindle and cutter block having an angular motion in a vertical plane given to it (this angular motion is the improvement claimed.) The inventor gives this angular motion to the well known boring and shaping spindle and cutter by making it move round an axis in the body of the frame, which axis being in a line with that of the shaft carrying the driving bevel wheel, the "gearing" cannot be interfered with, although the spindle should be made to move round a circle. The angular motion is regulated by the well known quadrant and endless screw so much used in other similar cases. In fact, the inventor takes the ordinary boring machine with its traversing saddle, and causes its spindle to take an angular motion in the manner described, instead of always remaining vertical as now made. The ordinary machine, with its cutter block always vertical, can only plane at one angle, whereas by this improvement the metal can be shaped to any angle, varying or uniform. *Patent abandoned.*

2147. A. Boyle and T. Warwick. *Improvements in the manufacture of the ribs and stretchers of umbrellas and parasols, and in machinery to be employed in the said manufacture.* Dated July 29, 1862.

These improvements in the manufacture of the ribs of umbrellas and parasols are effected by means of rolls in grooves in the peripheries, or cylindrical surfaces, of which suitably formed dies are inserted. The improvements in the manufacture of the stretchers of umbrellas and parasols may be effected either by the use of dies fixed in the rolls, or partly by the use of dies worked in a stamp or press. *Patent completed.*

2148. E. T. Hughes. *An improved process of refining the slag from blast, puddling, and other furnaces, and in the employment of the refined material for mortar, stones, slabs, ornaments, and other similar articles.* (A communication.) Dated July 29, 1862.

The patentee claims, 1, The improved system of changing the slag flowing in a glowing condition out of the blast, puddling, and other furnaces, by a rapid and complete covering with water, or any other steam developing fluid. 2, The application of the slag prepared for the manufacture of mortar, and also with the admixture of lime, or cement, for the manufacture of bricks, stones, slabs, ornaments, and other such-like articles. *Patent completed.*

2149. P. S. Devlan. *An improved composition to be employed for covering projectiles and the internal and external surfaces of vessels, which is also applicable to the manufacture of tubing, and to other useful and ornamental purposes.* Dated July 29, 1862.

This invention consists in an admixture and combination of paper, or other fibrous pulp, caoutchouc, or gutta percha, and any resinous gum; plumbago, may, also, if required, be mixed therewith. The proportions the inventor prefers are about 8 lbs. of fibrous pulp to half-a-pound of caoutchouc, or gutta percha, and 1 lb. of resinous gum, although such proportions may be varied without materially differing in effect. *Patent abandoned.*

2150. J. Norris. *Improvements in the arrangement or construction of ovens.* Dated July 29, 1862.

For the purposes of this invention, at the lower part of and supported within the chamber of the oven (which may be formed of brick work, or other suitable material, with air spaces, to prevent radiation of heat), a narrow space, or chamber is formed, the upper surface of which constitutes the bottom of the oven, and encloses the upper part of the furnace, or fireplace, formed by deepening the lower part of the narrow chamber near the centre to receive the fuel for the purpose of heating the oven. This chamber is made, by preference, of cast iron, either in one piece, or cast in plates, tubes, or other suitable forms, and the part in contact with the fire may be protected by fire bricks or tiles. At the ends, centre, or other part of the upper surface of the chamber over the furnace, or fireplace, narrow slots, or openings, are formed, from or near the front towards the back of the oven. These openings communicate with passages, or flues, which rise up, and are continued over the top of the oven, forming a narrow chamber, or flue, at the upper part thereof, from which the heat and products of combustion pass away by a suitable-flue, regulated by a damper, which flue, if desired, may be arranged to impart heat to water, or for other purposes. Thus it will be seen that the flues which rise from the closed chamber over the fireplace, or furnace, form the oven into two or more compartments, in which the articles to be baked, cooked, heated, or dried, may be placed upon shelves, or otherwise. A narrow air space is left between the flues forming the oven, as above described, and the inner sides of the chamber in which it is supported, suitable apertures being arranged for the introduction of air when required. Where several ovens of large dimensions are required to be fixed in one "setting," two or more fireplaces may be employed for heating the same if desired. *Patent completed.*

2151. C. T. Burgess. *An improved stand for beer and other casks.* Dated July 29, 1862.

This invention consists in constructing a stand for beer and other casks, in which the cask is made to tilt gradually forward with the decrease of the liquid in the cask. The stand consists of two parts:—The first is a pillar or frame for supporting a cradle in which the cask is placed. This cradle is a semi-circular frame, with flanges projecting from the upper and outer sides. The bearing surface of these flanges is curved or cam-shaped, and the flanges rest upon flat surfaces on the top of the frames. A bar projects forward from the semi-circular frame, which is bent up at front to receive one of the ends of the casks. In some cases, however, the patentee dispenses with the projecting bar. *Patent completed.*

2152. G. Waldie. *Improvements in colour printing.* Dated July 29, 1862.

This invention relates to a new system of colour printing, which is applicable to letter-press printing, lithography, calico printing, and to the printing of paper hangings. Under one modification, as applied to letter-press printing, as, for example, show bills, and other work, printed in straight lines, the several lines of type or ornament may be inked at one operation, with inks of various colours, and so produce with one printing an impression in several colours, which, in the ordinary way, would require several impressions in succession to produce. According to this modification the inking table over which the inking roller is passed is divided into longitudinal divisions, and the roller is guided by end flanges, so that the same part of the periphery of the inking roller always passes over the same division of the table. The divisions of the table are made to correspond to the width of the surfaces of the lines to be printed, or any other convenient width, and they are separated by grooves or spaces, so that the different colours cannot get mixed on the table or run together. *Patent abandoned.*

2153. J. Mapple. *Improvements in telegraphic apparatus.* Dated July 29, 1862.

This invention consists of a flat endless chain, known as a clock or watch chain, rotated by a train of clockwork, and the said flat chain is made to rub against an inking-roller supplied with common printing ink, and the strip of paper is made to press against the inked surface of the chain by the attractive force of an electro-magnet, and by these means the telegrams are traced in ink in lieu of indentations produced by the common Morse instrument. *Patent abandoned.*

2154. E. B. Clark. *Improvements in the manufacture of candles.* Dated July 29, 1862.

In carrying out this invention, the inventor proposes, instead of the ordinary mode of dipping, to place the tallow, or other material suitable for the manufacture of candles, in a cold or partly cold state, within a covered trough or receptacle, placed upon a suitable framing; one end of this trough or receptacle is open, and is provided with a corresponding block, across which is a series of holes, to which are secured polished metal dies of the required diameter of the candle. A bar is placed behind and across the block, within the trough, in the front of which bar wires are fixed, which pass through the centres of the dies. About the middle of the trough, and fitting closely thereto, is placed a plunger, which is caused to move towards the dies by means of racks and pinions attached to the back of the plunger within the opposite end of the trough: thus, when motion is imparted to the pinions by winch handles outside the trough, the tallow or other material contained therein is forced against the dies, and in passing through them is formed by means of the centre wires into hollow candles or tubes, which are then to be cut off at certain distances, as required, by a cutter or cutters working in front of the dies, or in a groove formed in the block near the mouth of the dies. The wicks of such candles are to be drawn through in a dry or partially dry state by means of wires. *Patent abandoned.*

2155. M. Henry. *Improvements in obtaining fibrous materials and paper pulp, in treating, cleansing, and scouring fibrous materials and fabrics manufactured thereof, in producing soap for the same operations, and in obtaining products from liquors used therein.* (A communication.) Dated July 29, 1862.

This invedtion has for one object the manufacture and application of an improved soap, suitable for employment in obtaining fibrous materials and paper pulp from plants, and in scouring, bleaching, improving (as to quality and appearance) and treating fibrous and textile materials and fabrics manufactured thereof. The aforesaid improved soap (herein called caustic soap) is produced by combining caustic alkalies in considerable proportions with saponifiable materials, or materials capable of saponifying, the alkalies being used in such large proportions that they become unable to dissolve, destroy, or injure animal or vegetable textile fibres, while, nevertheless, retaining their disintegrating power, that is say, their power of setting free or separating the fibres from the other extraneous matters combined therewith or adherent thereto. This caustic soap is manufactured by combining a concentrated solution of caustic alkali with a saponifiable material in a fluid state, and then stirring or agitating the mixture, and leaving it to stand or at rest. Resinous bodies and essences may be used in the manufacture of the caustic soap by dissolving them in the alkali before adding the other or saponifiable ingredient. In manufacturing the caustic soap for treating any particular plant, an oil or fat obtainable from that plant may be combined with the alkali. We cannot give space to all the details of the invention. *Patent completed.*

2156. G. Nock. *A new or improved safety or moveable self-acting crossing for railways.* (A communication.) Dated July 30, 1862.

In the crossing for railways ordinarily employed, the ends of the rails on either side the crossing point or frog are fixed. In this invention the ends of the rails are made moveable, that is, they have a slight motion about a centre or point at the chair, six feet, more or less, distant from the ends of the rails. The two ends of the rails are clipped and bolted together to suit the curve of the road, and sufficient play is left in the chair and in the holes through which the spikes pass to allow of the slight motion required. When the flange of the carriage wheel comes in contact with the guard rail, the carriage wheel on the crossing point or frog presses the moveable rails outwards, to accommodate the curve of the line. The periphery of the wheel thereby obtains a greater bearing, and the crossing points wear much longer than crossing points of the ordinary construction. The motion of the engine and carriage is very steady, and the passing from one line to another is not attended with the jarring motion which occurs when the ordinary crossing point is employed. The said new safety or moveable self-acting crossing is much safer than an ordinary crossing point. *Patent completed.*

2157. F. C. Warlich. *Improvements in machinery for dressing and shaping stone.* (A communication.) Dated July 30, 1862.

This invention is not described apart from the drawings. *Patent abandoned.*

2158. W. E. Gedge. *Improved means or apparatus for securing the safety of trains moving on railways.* (A communication.) Dated July 30, 1862.

The object of this invention is to prevent the rolling stock forming a railway train from leaving the rails during its locomotion. This object is attained by bringing into use, either on the permanent way of railways or on the vehicles used thereon, one or other, or a combination of several or all of the improvements hereinafter described, the first described being the most perfect, the second the most economical. The most usual causes of railway accidents are: 1, The severity of the curves. 2, Breakage of axles. 3, The mode of breaking, which, in stopping entirely the rotation of the wheels, causes them to slide on the rails, thus wearing them at a given point, and rupturing the integrity of the circle or crown of the rail, causing jerking or jumping on the rail, and subsequent possible breakage of axle, or departure from the line of rail. The apparatus forming the first part of these improved means for securing the safety of trains moving on railways may be divided into three principal parts. 1, A third or safety rail. 2, Two friction rollers turning horizontally on each side of the safety rail. 3, Of two nipples, chimneys, or trivets, forming boss or name to the axles of the friction rollers. And, first, as regards the third or safety rail which is laid down on wooden sleepers at curves (or other dangerous parts of the permanent way) between the ordinary rails, and is elevated slightly above them. Near the extremities, and to permit the introduction of the flange of the rollers, it has its lateral faces brought nearer together, giving to the rail at its spring the shape of a wedge, or the upper shoulder may gradually die away. The safety rail starts before the curve begins, in order that the train may travel on it before the locomotive arrives at the curve; or it may be used along the whole line of railway (except at crossings) if found desirable. In the second means (heretofore alluded to), the centre or safety rail is dispensed with, a modification being made in the ordinary rails by which the wheels of the carriage, and the base or block of the safety brake, are made to rest on a return provided with a shoulder, which fulfils the office of the safety rail before mentioned. The invention cannot be described in detail without reference to the drawings. *Patent completed.*

2159. J. and J. Hyde. *Certain improvements in governors for steam-engines, water wheels, mills, and for other similar purposes.* Dated July 30, 1862.

This invention is designed for the purpose of insuring the slightest alteration of the governor being transferred to the steam supply valve, and thus to render the governor more positive and sensitive in its action, and prevent inaccuracy from the adhesion or friction of any part. The improvement consists in the application and use of a train of gearing interposed between the governor and the steam valve for the above purpose. Upon the vertical shaft driving the governor a pinion is fixed, gearing with another pinion, which drives a shaft actuating bevel gearing, and a double catch-box, which is connected and disconnected by the movement of the ordinary lever acted upon by the governor. These upper or lower catches being thrown in or out of gear regulates the admission of the steam by opening or closing the steam supply valve. *Patent abandoned.*

2160. B. Bailey. *Improvements in means or apparatus for cutting chaff and other vegetable matters, which improvements are also applicable to cutting or mowing short or lawn grass.* Dated July 30, 1862.

This invention relates to arranging and supporting the cutters in apparatus commonly called chaff-cutting machines. The patentee employs a pair of cutting blades supported by ribs or arms from a central axis in front of the mouth of the trough supporting the matters to be cut, and in such manner that all parts of the cutters are concentric or nearly so to such axis, whilst the cutting edges are inclined diagonally thereto, but in opposite directions one to the other, so that, when caused to revolve, one cutting edge will begin its cut at one end thereof, and finish at the opposite, and supposing this to be from right to left, the other cutter will begin at the left, and progressively cut to the right. These diagonal cutters act with a fixed cutter forming part of the feed mouth. The cutters are adjustable, and the parts between them are open to admit of the free passage of the matter cut. This arrangement of cutters is also applicable to lawn mowing machines. *Patent completed.*

2161. H. White. *Improvements in shirt collars.* Dated July 30, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2162. W. Wanklyn. *Improvements in apparatus for opening and conditioning East Indian and other tightly-compressed cottons.* Dated July 30, 1862.

This consists in improved apparatus for opening and conditioning, or bringing into a condition suited for the processes of preparing and spinning, East Indian and other cottons that have been packed in compressed bales. In performing the invention the patentee makes use of a steaming chamber. The chamber which he uses, by preference, is snpported by trunnions, and has a perforated false bottom and a steam-tight lid, which is supended to a chain or cord and counterbalanced. Steam is admitted to the chamber by a pipe, in which is a tap, and the steam should be at a high pressure. He also uses a syphon or other suitable apparatus to the steam-pipe, to prevent the water of condensation entering the chamber with the steam, which he prefers to use in as dry a state as possible. The cotton, when taken out of the bale, is placed in the chamber, and when full, or nearly so, the lid is put on, and steam is admitted. As soon as the steam has had time to permeate and heat the cotton, the lid is removed, and the steam chamber is swivelled partly round on its trunnions to allow the cotton to be raked into a truck or other carriage, in which it is removed to the room in which the subsequent operation is to be performed. A tap is inserted in the steam chamber, under the false bottom, to discharge the water that may have accumulated there. *Patent completed.*

2163. J. Benyon. *Certain improvements in looms for weaving.* Dated July 30, 1862.

This relates to the taking-up motion, and consists in an improved arrangement of parts for giving a positive take-up motion to the roller on which the fabric is wound as it is delivered by the loom. The improved arrangement of parts may be applied to the warp beam to effect a positive let-off motion. *Patent completed.*

2164. G. H. Birkbeck. *Improvements in the means or processes employed for preserving timber from decay or destruction.* (A communication.) Dated July 30, 1862.

For the purposes of this invention a compound resembling soap is prepared by combining a solution of sulphur or metallic oxides, or both, combined with fatty acids, which are insoluble in water, but are readily dissolved in rough naphtha, or in American or Canadian petroleum, in the state in which it is obtained from the oil wells of those countries. The method which is preferred of preparing the compound consists in boiling "claine" or "magaric acids" (residual products obtained from the manufacture of stearine or other similar description of candles) with a metallic oxide. A little water is introduced into the vessel in which the mixture is boiled to form the salts, in order to prevent the decomposition of the fatty matters. The formation of the soapy compound is readily and quickly accomplished in an open metal vessel, the mass being constantly stirred or kept in motion. The soapy compound thus prepared is then dissolved in rough naptha or petroleum in a closed boiler (by preference, of wrought iron or copper) provided with a bent tube or worm, connected with an ordinary condensing apparatus, so that the fine naptha, which is distilled over by boiling the soap into the rough naptha or petroleum, is thus preserved, and is a valuable product resulting from the process. The solution thus prepared may be forced into the wood by pressure in various ways, as is well understood in impregnating timber with other solutions; or the timber may be impregnated by boiling it in the solution contained in a closed boiler. *Patent completed.*

2165. W. Clark. *Improvements in gas burners.* (A communication.) Dated July 30, 1862.

This relates to the application of a small cap or thimble of wire gauze to gas burners, ecpecially those called fish-tail burners, whereby to increase the lighting power for a given quantity of gas consumed, and, consequently, lead to great economy in its consumption. This cap will be found very efficacious, as it introduces a metallic body into the centre of the frame, which thus becomes heated, while it further counterbalances or regulates the initial pressure of the gas. *Patent completed.*

2166. T. Holt and F. L. Stott. *An improved composition or compositions for protecting polished surfaces of iron and steel against oxidation, and for renewing and improving the polish of such surfaces.* Dated July 30, 1862.

This consists in a combination of lime, oils, and fatty matters, camphor, and a solvent of camphor. The inventors prefer to use 40 parts of lime and 54 parts of lead, mutton suet or beef fat, 1 part of oil of cloves, 4 parts of camphor, and 1 part of turpentine. *Patent abandoned.*

2167. W. Norman. *Improvements in tables and drawers or other sliding receptacles.* Dated July 30, 1862.

This consists in the adaptation of metal bars to the framework of sliding tables, which bars are embraced by metal clips carried by a separate framing. These bars and clips, therefore, constitute mutual guides, so as to allow of an expansion of the table which is carried by the said framing, and the patentee adopts a similar method of construction for drawers, shelves, and other such like sliding receptacles. *Patent completed.*

2168. J. W. Dixon, jun. *Improvements in coffee urns.* Dated July 30, 1862.

Here the patentee takes a metal ring and covers it with muslin, and the muslin is held in its place by a second ring fitting with the first, and the fabric is nipped and held between the two. These two rings being thus put together, they are then fitted into an annular ridge at the bottom of the urn. To fix the muslin properly it is necessary to lay it down flat, then to place the first ring in the centre of it; the corners of the fabric are then turned in over it, and fixed in the inside ring. The second ring carries a strainer of perforated metal; this the patentee makes in the form of a flat plate or disc, which is soldered to the ring, and has a truncated cone also of perforated metal attached to it at the centre; and projecting upwards on this the coffee is placed, and boiling water being poured in it rapidly forms an infusion which can be drawn off by a tap at the lower part of the urn. *Patent completed.*

2169. J. W. Woodford. *Improvements in machinery for raising or forcing water.* Dated July 30, 1862.

Here a vertical shaft is used, which turns in suitable bearings above the case or cylinder hereafter mentioned. The lower end of the shaft is hollow, and it steps on to an upright fixed conical bearing by which the shaft is supported. The shaft receives motion from a steam-engine or other power, by a strap which acts on a drum or pulley on the shaft, such drum or pulley being arranged to be fixed in any required part of the shaft. At its lower end the shaft passes through a fixed case or cylinder, which has one, two, or more tangential outlets, with rising pipes fixed thereto; when the two tangential outlets are used, they are formed at opposite sides of the case or cylinder. On the lower end of the shaft are fixed two bent or curved arms, to which bent or curved plates or blades are fixed. These arms and the blades are curved back from where they spring from, or are affixed to the upright shaft. The upper cover of the case or cylinder is close, except where the shaft passes through it, whilst in the under cover there is a central opening for the passage of water into the interior of the case or cylinder. In constructing framing for this machine, four vertical angle irons are used, fixed at the four angles of the base plate to which the case or cylinder is affixed, and these angle irons are framed or stayed together at intervals. In order that such framing may be convenient for fixing and unfixing in places where the machine is to be used, it is preferred that the upright angle irons should be made of convenient lengths, and be arranged and formed conveniently for the ends thereof going together, and being fixed readily by screw bolts and nuts or otherwise. *Patent completed.*

2170. E. F. Prentiss and R. A. Robertson. *Improvements in obtaining products from rock oil, coal tar, and other like mineral substances in a more or less pure or deodorized state, and in the appuratus to be used therefor, and which is also applicable to distillation in general.* Dated July 31, 1862.

We cannot here give space to the voluminous details of this invention. *Patent completed.*

2171. W. Weild. *Improvements in machines for cutting, shaping, rolling, drilling, screwing, milling, and fluting metals.* Dated July 31, 1862.

The first part of this invention consists in the arrangement of machinery for cutting, shaping, and rolling combined in one machine. This compound machine is more especially adapted for the manufacture of fire-box stays or bolts for locomotives and other boilers. The second part relates to an improved arrangement of machinery for screwing such stays in a most perfect and rapid manner, and it consists in giving rotary motion to three steel screwed rollers placed near to each other, and revolving in one direction. 3, In the arrangement and construction of a drilling machine with one or more drilling heads on one bed; each head has a separate and independent motion in a horizontal and lateral direction, and also an independent rotary and vertical section of the drill. 4, In certain adaptations and modifications of a machine for manufaduring rollers for spinning, for which letters patent were granted to the present patentee, bearing date the 20th September, 1859 (No. 2139); and it consists in applying the method of milling flutes in rollers, for spinning to milling, or roughening the surface of rollers to be used as self-acting temples, and the taking-up rollers in weaving. 5, In a new method of fluting rollers for preparing and spinning. This invention is not described apart from the drawings. *Patent completed.*

PROVISIONAL PROTECTIONS.

Dated Oct. 24, 1862.

2868. J. Wright, 12, Copthall-court, civil engineer. Improvements in the construction of seamless stays. (A communication.)

Dated Nov. 25, 1862.

3162. W. B. Caulfield, 30, Queen-street, City, stationer. A new kind of porous stems for tobacco pipes.

Dated Dec. 30, 1862.

3479. W. Clark, 53, Chancery-lane, engineer. Improvements in governing apparatus. (A communication.)

Dated Jan. 9, 1863.

72. C. Worssam, Commercial Wharf, Kingsland-road, engineer. An improved lithographic press.

Dated Jan. 21, 1863.

177. J. W. Meears, 4, Whistler-court, Cannon-street, gentleman. A new and improved method for making sash frames and sashes, and suspending the same by atmospheric or gas pressure.

Dated Jan. 26, 1863.

227. J. B. Fell, Sparkbridge, near Newton in Cartmel, engineer. Improvements in working railway engines and carriages on steep inclines.

Dated Jan. 28, 1863.

255. S. W. Francis, Gray's Inn-road, shutter maker. Improvements in revolving shutters.

261. B. l'A. Bromwich, Charterhouse-square, gentleman. An improved mode of obtaining and applying motive power.

Dated Jan. 29, 1863.

263. T. A. Weston, Birmingham, mechanical engineer. A new or improved coupling and break for transmitting or regulating or arresting motion.

264. J. B. E. Louit, ainé, Bordeaux, gentleman. Improvements in glasses termed chimneys, used for gas or other lights.

267. J. Pouncy, Dorchester. Improvements in obtaining, transferring, and printing from photographic pictures or images, also in peparing materials for the same.

269. J. Nadal, Brook's-market, Brook-street, Holborn. Improvements in fountains.

271. C. H. G. Williams, Rumford-street, Glasgow. Improvements in the manufacture of red colouring matters.

273. G. Blake, Trowbridge. Improvements in apparatus for heating and warming.

275. J. Sainty, Burnham, agricultural implement manufacturer. Improvements in feeding troughs for sheep and other cattle.

Dated Jan. 30, 1863.

279. W. F. Gedge, 11, Wellington-street, Strand. Improvements in cones, or forms, for moulding refined sugar. (A communication.)

281. N. P. C. Lloyd, 1, Liverpool-street. An improved atmospheric engine, applicable to purposes to which steam, horse, wind, and water power is applied.

Dated Jan. 31, 1863.

287. J. Grossmith, 85, Newgate-street, merchant. An improved mode of producing the aura electric gas.

289. W. Drummond, Bank of England. Improvements in apparatus for stopping the supply of gas to burners when the light is put out.

290. W. A. Lyttle, Andover Lodge, Albion-road, Hammersmith, gentleman. Improvements connected with cigars and other tobacco-smoking appliances.

291. E. B. Wilson, Parliament-street, Westminster, engineer. Improvements in supplying air, gases, steam, or fluids, to iron and other furnaces, and to engines and vessels requiring such supply, and in the apparatus employed therein.

Dated Feb. 2, 1863.

293. E. H. Massey, 15, Pine-grove, Crown-street, Liverpool, painter. Improved preparation or compositions for coating and colouring the walls, ceilings, and other parts of buildings.

295. A. Forbes, Canal-terrace, Aberdeen. Improvements in means or apparatus for soldering together parts of vessels formed of tin or tinned plate.

297. R. H. Frith, Leinster-road, Rathmines, civil engineer. Improvements in manufacture of paper.

299. W. Clark, Quadrant-road, Highbury New-park, engineer. Improvements in armour plated and other ships.

Dated Feb. 3, 1862.

301. T. Raworth, Leicester, elastic web weaver. Improvements in looms for weaving ribbons, elastic webbing, and other narrow fabrics.

303. S. Oddy and E. Oldfield, Adelphi Iron Works, Salford, machine makers. Certain improvements in carding engines.

305. A. T. Blakely, Parliament-street, and J. Vavasseur, Southwark, engineer. Improvements in projectiles for ordnance.

307. W. G. Valentin, Royal College of Chemistry, Government School of Mines, Oxford-street, chemist, and F. Levick, Blaina, Monmouth, iron master. Improvements in generating combustible gases, and in the apparatus employed therefor.

Dated Feb. 4, 1863.

309. G. Harton, North-road, Highgate. Improvements in wood paving.

311. T. E. Tallent, New Church-street, Bermondsey. Improvements in the manufacture of leather, and in machinery for that purpose.

313. G. Haseltine, 12, Southampton-buildings, Chancery-lane. Improvements in the mode of uniting metallic surfaces. (A communication.)

315. J. J. Hays, Hitchin, Hertford, gentleman. An improved hot air stove, where peat charcoal is the fuel employed, and for the method of using peat charcoal, or other suitable fuel, in connection with the said stoves, or other stoves, for the purpose of purifying or filtering the gaseous products of combustion.

316. L. J. H. Marville, 2, Rue Ste. Appoline, Paris, merchant. A new kind of covering for the ears, made of india rubber, gutta percha, or other materials.

317. Z. M. Parkes, 7, Upper Park-place, Plumstead-common, gentleman. Improvements in iron and other metal bond for use in building.

319. B. Russ, Bristol, Gloucester. Improvements in the construction of iron ships and vessels, and of armour applicable thereto.

321. J. A. Manning, Inner Temple, Esquire. Improvements in the treatment of night soil and other waste products, and for the manufacture of manure therefrom.

322. W. Stokes, builder, Edgbaston. Improvements in the construction of window sashes, whereby the same are rendered more weather proof and secure against draughts and burglars, and permit the outside to be cleaned with the facility of the inside.

Dated Feb. 5, 1863.

323. W. T. Mabley, Altrincham, Chester, mechanical engineer, and W. T. Cheetham, Ashton-under-Lyne, mechanical draughtsman. Improvements in blowing organs and other such musical instruments, parts of which improvements are also applicable to obtaining motive power for other purposes.

325. W. Betts, Wharf-road, City-road, capsule manufacturer. Improvements in apparatus for applying metallic capsules to bottles.

327. E. Ingham, Halifax and Bradford, dyer and finisher. An improved apparatus for, and means of, dyeing wool in the silver, from which "mixture yarns" may be drawn.

328. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in machinery for supplying and spreading wool and other filamentous materials on belts, tables, and other surfaces, to be afterwards carded and otherwise acted on. (A communication.)

320. J. Paterson, Staining-lane, warehouseman. Improvements in buckle and hook fastenings.

330. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in apparatuses for tuning pianofortes. (A communication.)

Dated Feb. 6, 1863.

331. B. F. Bates, Morley's-hotel, Strand. Improvements in cannon and in projectiles to be used therewith. (Partly a communication.)

333. T. Blakeley and B. Meakes, Bread-street-hill, Cannon-street. An improved lead and stone pencil sharpener.

335. G. Stevens, Victoria-terrace, Camberwell. Improvements in means or apparatus for effecting a regular supply of air or aeriform fluids for various purposes.

337. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in carding engines, whereby slivers are formed into threads ready for spinning. (A communication.)

339. J. Price, 84, High-street, Southampton, wholesale ship chandler. Improvements in signal lanterns suitable for being used in open boats.

341. A. Ellissen, Warwick-road, Maida-vale, merchant. An improved method of treating sheeting and plates of iron to be used in ship building and marine constructions for protection against marine animals and marine plants.

Dated Feb. 7, 1863.

343. J. Sirou, Castel Sarrazin, Tarn et Garonne, France. contractor of public works. A new medicinal preparation for internal and external application.

345. G. Turner, 13, Rose-terrace, Brompton, machinist. Improvements in means or apparatus for mincing or cutting meat or other substances.

349. J. James, 12 and 13, Red Cross-square, Cripplegate. An improved covering for hooped skirts.

351. M. Hackforth, Bentinck-street, Manchester-square, painter and decorator. Improvements in shades or reflectors for lighting purposes.

353. D. Groucutt, Coseley, iron master. An improvement or improvements in the manufacture of iron for making nails.

Dated Feb. 9, 1863.

357. D. Law, ironfounder and engineer, and J. Downie, engineer, Glasgow. Improvements in traction engines or common road locomotives.

359. H. and J. Smith, Bury St. Edmunds, implement makers. Improvements in drills or machines for depositing seed and manure.

Dated Feb. 10, 1863.

361. J. Crosby, Audenshaw, manufacturer, and J. T. Smith, Bury, engineer. Improvements in carding engines for carding and drawing flax tow, in part applicable to carding cotton or other fibrous substances.

363. R. Burley, Glasgow, hammer handle maker. Improvements in handles for hammers, mallets, picks, mattocks, and similar tools.

365. M. Cartwright, Hoxton, dentist. Improvements in combining plastic substances with metals.

367. W. Whitaker, Bradford, merchant, and W. Tongue, engineer. Improvements in apparatus and processes for steeping, boiling, washing, bleaching, and dyeing, fibrous materials or slivers, slubbings, rovings, yarns, or woven fabrics of the same.

Dated Feb. 11, 1863.

371. J. Duckworth, Pilkington, near Manchester, size manufacturer. Improvements in the manufacture of paper.

375. W. Symington, Glasgow, manufacturer. Improvements in weaving, and in apparatus therefor.

377. E. Humphrys, Deptford. Improvements in apparatus for steering ships.

PATENTS PROTECTED FOR SIX MONTHS BY THE DEPOSIT OF A COMPLETE SPECIFICATION.

Dated Feb. 18, 1863.

414. M. Ohren, Sydenham. Improvements in the construction of gas-holders, and in the mode of rendering gas-holders self-acting.

LIST OF SEALED PATENTS.

Sealed Feb. 20, 1863.

2362. H. P. Hughes.
2364. J. and B. Harrison.
2370. A. Crichton.
2374. R. Sims.
2384. J. J. Potter.
2389. J. J. Moeckel.
2400. G. W. Dyson.
2402. P. W. Mackenzie and S. W. Smith.
2406. E. T. Hughes.
2407. E. C. Harding and C. Doody.
2414. J. Walker.
2428. R. Glanville.
2468. C. W. Williams.
2537. J. Whines.
2580. H. R. Fanshawe.
2910. A. Krupp.

Sealed Feb. 24, 1863.

2379. R. A. Brooman.
2381. J. G. Nutting.
2390. E. Lachenad.
2391. W. Husband.
2401. W. Owen.
2408. F. Le Conte.
2411. J. Meyer.
2416. J. Ellis.
2417. J. Whitehead.
2418. E. G. Fitton.
2419. J. Watt and T. S. Havialde.
2147. J. Platt and W. Richardson.
2449. R. P. Coles.
2471. J. Whitehead.
2522. H. J. Lewis.
2529. E. G. Chant.
2637. J. Brown.
2650. W. and W. Carrick.
2709. C. Chinnock.
2775. J. H. Johnson.
2836. G. T. Bousfield.
2934. A. Guild.
2979. J. H. Johnson.
3002. T. Brown.
3052. A. Graemiger.
3061. E. S. Ritchie.
3100. N. Thompson.
3203. T. Evans.
3209. J. Anderson.
228. W. E. Newton.

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

From the *London Gazette*, Feb. 24, 1863.

2764. H. Bridstone and J. Alcock. Folding, measuring, and hooking woven fabrics.

2765. E. Barlow, J. Clough, and F. Hamilton. Driving cotton gins.

2766. J. Snider. Hansom cabs.

2769. M. Cartwright. Artificial teeth.

2773. O. J. and J. Showell. Glass roofs and roof lights.

2777. W. Wilson. Drawing-room bagatelle and billiard table.

2778. J. H. Jenkinson. Drinking fountains.

2782. W. Pope. Coating the sides of ships, batteries, forts, or other like places with defensive armour plates.

2790. W. Barningham. Permanent way.

2800. J. Robinson. Protecting the submerged portions of iron ships.

2801. E. Hely, jun. Envelopes.

2803. J. Summerton. Harrows.

2804. H. Wickens. Making nails. (Partly a communication.)

2807. G. T. Bousfield. Manufacture of iron and steel. (A communication.)

2812. J. Bentley. Forming and pressing felt hats.

2813. B. Lauth. Polishing metals.

2814. R. A. Brooman. Doubling and twisting threads. (A communication.)

2819. G. Haseltine. Forging cannon and other heavy articles. (A communication.)

2822. N. R. Hall and M. L. Parnell. Thermometers.

2826. J. H. Johnson. Boiling liquids and cooking or preparing food. (A communication.)

2834. J. T. Cooke. Battens for weaving.

2835. R. A. Brooman. Waterproofing. (A communication.)

2847. E. W. Hughes. Turntables and turnbridges.

2853. A. Chaplin and G. Russell. Obtaining fresh water by evaporation.

2855. W. Clark. Sewing machines. (A communication.)

2863. A. J. F. V. Brepson. Siphoidal cistern.

2877. W. Clark. Construction of the joints of pipes. (A communication.)

2883. J. Chattwood. Ventilating.

2888. W. J. Williams. Field rakes. (Partly a communication.)

2921. J. Unsworth. Steam-engines.

2948. T. Gibson, T. Hall, and T. Davison. Railway breaks.

3010. C. O. Heyl. Extracting oils.

3166. W. Longley. Making bricks.

3175. A. V. Newton. Preparing oxide of zinc. (A communication.)

3204. W. Clark. Cutting cork. (A communication.)

157. E. Sable. Artificial stone. (A communication.)

176. S. Blackwell. Applying water to animals.

225. F. Tolhausen. Carding fibrous materials. (A communication.)

239. J. Edmonson and T. Ingram. Looms and apparatus for weaving.

265. J. Mackenzie. Shaping machines for curvilinear surfaces.

282. W. E. Newton. Couplings for railway carriages. (A communication.)

301. T. Raworth. Weaving ribbons, elastic webbing, and other narrow fabrics.

The full titles of the patents in the above list can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners' office particulars in writing of the objection to the application.

PATENTS ON WHICH THE STAMP DUTY OF £50 HAS BEEN PAID.

435. A. Belpaire.
440. H. D. P. Cunningham.
508. J. H. Johnson.
587. J. Eccles.
475. C. Schiele.
723. J. Aspell.
755. C. Ashworth.
465. Sir C. T. Bright.
527. T. Silver and J. Hamilton.
564. R. H. Collyer.
522. G. Jenkins.
562. W. E. Newton.
605. J. Howard.
624. A. Paget.
664. W. E. Newton.
485. R. A. J. Dujardin.
494. J. Pegg.
499. E. Mucklow.
503. W. H. Muntz.

PATENTS ON WHICH THE STAMP DUTY OF £100 HAS BEEN PAID.

452. J. S. C. Heywood and G. Lloyd.
420. W. G. Merrett.
561. E. Schischkar.
431. J. Freer.
470. H. Loveridge.
505. T. T. Jopling.

THE

MECHANICS' MAGAZINE.

LONDON, FRIDAY, MARCH 6, 1863.

ON WAVE MOTION.

A THIRD volume of "Transactions of the Institution of Naval Architects" has just been issued to the members and associates. It contains reports of the papers read at the last session, with the discussion upon them. It is illustrated by numerous steel engravings and woodcuts, executed in the best manner, and is, as a piece of book making, most creditable to the Institution. Its real value must, however, be tested by quite another standard, and we are very glad to be able to say that it is a most valuable addition to our naval science.

At the preceding session, a paper was read by Mr. Froude, a pupil, we believe, of the late Mr. Brunel, and brother to the well-known historian of that name, upon the rolling of ships. His attention was directed to the subject by Mr. Brunel in connection with the "Great Eastern," and with the object of discovering the probable sea-going qualities of that ship. He soon observed that the most noteworthy phenomenon connected with the motions of a ship under the impulses of the waves, was the gradual accumulation of angle during several successive rolls; the cumulative action growing up into a maximum, and then dying out by very similar gradations. The ship having remained steady for a moment, a nearly similar series of excursions commences and is reproduced.

He observed that the very large angles of rolling which are occasionally reached, are never due to single wave impulses, but are invariably the cumulative results of the operation of successive waves. This view of the facts was supported by the Rev. Canon Moseley, who presided on the occasion when the paper was read. Alluding to the way in which the repetition of the impulses exerted upon the floating body is made to modify the oscillations, he said:—"If, when a vessel first rolls, and then rolls back, at the instant that it has got to the extreme roll back you apply a second impulse, you very considerably increase the amount of the succeeding oscillation; and, if you wait till the third extreme roll and then apply a third impulse, you impel her through a still further angle; and so you may go on, applying such impulses at those particular periods. The effect of such accumulation of motion is displayed in the case of suspension-bridges, some of which have been brought down by the steady marching of a body of troops, owing to the fact of the steps of the troops synchronizing with the oscillations of the bridge."

The question, therefore, which proposed itself to Mr. Froude, was,—"What is the cumulative result of the continuous action of a series of consecutive waves operating on a given ship?" and, as a most important step towards this discovery, "what attitude does the ship, at each instant, seek to occupy in reference to the wave on which she floats, and what measures the force which urges her to take that attitude?" In supplying an answer to the question, Mr. Froude has rendered most important service to this department of scientific research. He tells us that, to a particle of fluid or floating matter at any point in the surface of a wave, or of any non-horizontal volume of free fluid, a tangent to the surface at the point in question is virtually level. If, therefore, the configuration of such a floating particle were such as to give it stability in still water, so that it would always endeavour to place its "axis of equilibrium" in a vertical position, then were this same particle floating on a wave, it would, by virtue of the same property of stability, endeavour to place its "axis of equilibrium," not vertical, but *at right angles to the surface of the wave.*

As an illustration of the way in which a motion of translation modifies the ordinary effects of gravity in such cases, he refers to the fact that, if a spirit level is attached at the centre of oscillation of a pendulum, and is adjusted level when the pendulum is at rest, then upon setting it in motion it will be found that, if the pendulum is allowed to oscillate freely, the spirit will continue to indicate level at all angles of inclination. He made, moreover, the following experiment, to test the accuracy of this principle. A float was formed of cork, somewhat like a small life-buoy, about four inches in diameter; a mast was planted obliquely in one side of it, with its apex perpendicular over the centre of the float; a small plumb-bob was suspended from this, having its centre at the level of the centre of buoyancy of the float, and occupying, when in still water, the centre of the ring. When this was set afloat in a trough fitted with apparatus for generating waves, while the plane of its floatation followed the slope of the waves, the plumb-bob remained nevertheless, so completely central, that to an eye resting on it it was difficult to believe that the surface was really disturbed by waves, though, on watching the sides of the trough, it was plain that the wave slope ranged up to 15 degs. or 20 degs., the plumb-line, at the same time, deviating to the same extent from the perpendicular; and, Mr. Froude says, that in trying the experiment in the sea, he has seen the bob remain equally central, while the float rested in the hollow front of a breaking surf wave, even where the surface was considerably "overhanging," so that the line sloped upward from the point of suspension.

In the present volume there is a paper by Mr. Crossland, of the Department of the Controller of the Navy which, while it establishes on a firm mathematical basis the main positions of Mr. Froude, shows that some of his views require to be modified.

The feeling expressed by Dr. Woolley with regard to Mr. Froude's paper, was shared by other mathematicians. He said that while he considered the memoir to be a most valuable and suggestive contribution to the science of naval architecture, by the perusal of which we could not fail to have our ideas of the subject enlarged, he yet doubted the sufficiency of his theory to account for all the phenomena presented by a ship rolling in the trough of the sea. He doubted whether when a body of any kind floated on a disturbed fluid it would necessarily accept the dynamical conditions of the fluid it displaced, and he did not consider the experiment described above to be at all conclusive. Notwithstanding this, he went on to say, "I think that in the absence of a more precise theory—a theory which I fear there is little prospect of our being able to arrive at—Mr. Froude's speculations possess the greatest interest and value, and approximate in their *results* to the case presented by natural phenomena."

The suspicions which this gentleman had formed were justified by his able pupil, Mr. Crossland, in the paper referred to above, in which he pointed out the limits of his adhesion to the theory of Mr. Froude, and securely established that which he accepted.

Dr. Macquorn Rankine followed on the same subject, suggesting a simpler mode of arriving at the differential equation of the ship's motion, by assuming the trochoid to be the approximate figure of the wave instead of the curve of sines.

He shows also the cause of the difficulty in estimating correctly the height of waves from the deck of a vessel. The passenger, looking at an advancing wave from a vessel which is situated on the sloping side of the contiguous wave, takes as the horizontal a plane which is a tangent to the side of the wave at his position, and which appears to him to be the level. Under such circumstances the apparent height of the wave would sometimes be as much as three times the real height.

The practical conclusions to which we are led by these papers, are as follow:—

That every ship has a certain time of oscillation, depending on her form and on the disposition of her weights and cargo. This time is uniform, and is not affected by the force or rapidity of motion of the waves.

The distance between the crests of the waves is also uniform for certain conditions of wind and sea, and there is therefore, a certain uniform interval between the blows of successive waves upon a ship exposed to them.

If this interval is, under any circumstances, the same as the time taken by the ship in making each roll, then the ship will be capsized.

The object of the naval architect must be to make the time of oscillation of the ship as different as possible from the average periods of the waves.

These periods are usually shorter than the time of the ship, it is therefore desirable to make that time as long as possible—in other words, to make the ship roll slowly.

Happily, the heavy armaments and armour of our modern ships tend to increase this time, and in this respect there is also a decided advantage in having the armour and the guns as far as possible from the middle of the ship.

In addition to these, there are very valuable papers on the Magnetism of Iron, and Compass Deviations, by the Astronomer-Royal, by the Superintendent of the Compass Department at the Admiralty, by Archibald Smith, Esq., M.A., F.R.S., and by the Secretary to the Liverpool Compass Committee.

These are followed by numerous papers on Practical Questions in Shipbuilding and Marine Engineering, some of which we hope to be able to notice.

CALIFORNIA AND GOLD.

(Continued from page 114.)

IN our first notice of M. Laur's interesting account of the Californian gold workings, we traced the gradual progress of these remarkable undertakings, and their development from a mechanical point of view. We will now describe the application of the *sluice* system to the *mountain placers.*

The *placers* of the mountains are sandy deposits mingled with metallic gold, formed by the action of the waters on the primary auriferous rocks, during the first period of the diluvian epoch; and which were spread by the same agencies over the western slopes of the Sierra-Nevada mountains. These strata, disturbed to some extent by the geological revolutions of successive ages, still extend over a large surface of territory. The auriferous layers extend about 150 kilometres (93 miles) from south to north, and 40 kilometres (24 miles) across the three counties of Sierra, Placer, and Nevada. They form high table lands or terraces on the slopes of the Nevada mountains, and these gold strata generally crown the valleys, 150 to 200 metres deep, excavated by the waters in the living rock. The layers of gold gravel extend to a great depth, being seldom less than 12 metres thick (39 ft.) M. Laur states that he has seen them 60 metres (196 ft.) deep in certain places. These deposits contain gold throughout the entire mass; but there is more gold to be found in the large pebbles at the bottom than in the finer sand at the top.

Each layer has thus a richness according to its particular level, but experience has shown that the whole series of layers affords a tolerably equal average of gold throughout the whole expanse of the formations.

This gravelly soil could, probably, cover a surface of 15,000 square kilometres (5,775 miles), with a layer of auriferous sand, at least 10 metres (32 ft. 8 in.) deep. It can be regarded as an auriferous deposit giving a constant average of produce, like coal strata, or beds of ironstone, and can, therefore, be worked on a similar scale to the latter minerals. The *general average* of gold in this formation is very low, if measured by the cubic metre. Mons. Laur states that he is probably above the mark in estimating the general average of gold contained in the alluvium as worth 1f. 50c. per cubic metre. What a wide difference with these times when the sands of some of the Californian rivers gave up 9 per cent. of their weight in gold! Nevertheless, the Californian miner, even out of this poor alluvium (worth, at the most, 1f. per ton), produces, per day's work of one man, 220 grammes (7 oz. troy) of gold, of the value of 750f. We will now see how this is effected.

The gold miners of the Nevada mountains call to their aid the power of great currents of water. These water currents are supplied by the snows covering the Nevada chain of mountains during six months of the year; by the lakes in the neighbourhood, and by the mountain torrents. The miners have built immense water reservoirs, and conduct the water by means of canals, tunnels, and aqueducts, down the steep slopes of the hills. The main stream is fed upon the auriferous strata by means of secondary streams. The length of these canals, for the whole of California, probably exceeds 8,000 kilometres (4,960 miles). The water drops on to the *placer* from a canal placed as high as possible above the cutting that is being worked. The old excavations are thus at the foot of the aqueduct. The auriferous gravel is cut perpendicularly from the top to bottom, from the grass above to the rock below. This perpendicular cutting extends like an immense wall, 40 or 50 metres (130 to 165 ft.) high, and several thousand metres long; at the foot of which are placed, at intervals, the wooden erections for operating upon the mass of alluvium. The excavations are made by means of regular hydraulic batteries. The water of the upper canal is received by a large conduit made of iron plate, and it drops from the whole height of the trench. The water current has thus a fall of 40 or 50 metres (130 to 165 ft.). It descends at last through a final pipe of smaller diameter, and through which opening, guided by the miner, the water plays upon the wall, and detaches great lumps of gravel, thus sapping the wall to its foundation.

Three water jets are used to produce the maximum effect. The gravel seems to melt away under the action of the streams of water. Torrents of mud and large cakes of earth rise up at the foot of the cutting; they are then conducted by extensive trenches into a subterranean gallery, where they are recived by broad deep sluices. The gold gradually separates itself from the torrents of mud, and drops to the bottom, to which it adheres, as it gets amalgamated with the mercury. The barren substances then flow onward, and are disgorged into the hollow of some deep valley, where they remain till displaced by the winter torrents.

Such are the main principles upon which the auriferous deposits of the Nevada *placers* are worked. We will now give some of the results, and will take as an instance the *Eureka* workings, near San Juan. The auriferous deposit measures about 43 metres (145 ft.) thick at this place. The undertaking employs four jets of water, furnishing about 15,000 cubic metres (525,000 cubic feet) of water per ten working hours. The miners break down and wash about 2,808 cubic metres (98,280 cubic feet) of alluvium with this water. The expenses are as follow:—

Water bought of the canal companies, per day . .	540 francs.
Hand-labour and superintendence	86 ,,
Tools	50 ,,
	676 ,,
The gold produces on an average per working-day . .	3,000 ,,
Net profit per day is thus .	2,324 francs.

Four men are sufficient to conduct the entire undertaking. We can perceive, by combining the above figures, that the quantities of gold produced by each cubic metre of earth is worth 1f. 7c.; the gold corresponding to each square metre of surface is worth 45f. 95c. The net profits for each man's daily work are, therefore, 581f.; the rough produce being 220 grammes (7oz. troy) of fine gold. By comparing the primitive plan of gold washing by means of a dish with the present method of the water jet, it will be seen that, to wash a cubic metre of sand, would require three days and three-quarters according to the old plan, while it only requires one-sixth of a minute with the new method.

Each hectare (nearly 2½ acres) of the alluvium thus contains 460,000 francs worth of gold dust. Some time before M. Laur left San Juan, a mine was sold near the Eureka workings. The mine measured twenty acres, and it was divided into twenty-four shares. Each share was sold for about 6,000f. cash. The hectare (2½ acres) thus cost 96,000f.

Such is the progress that has been acheived up to the present. M. Laur considers that important additional improvements can be made. Present results show that it is sufficient to have plenty of water and to be able to drop it down at great heights, in order to produce large quantities of gold. These two conditions of the problem can be resolved on an extensive scale in California. To further demonstrate this, we will take another mountain *placer* as an instance—the placer belonging to the mine of San Juan.

This placer appears like an extensive table land of gravel. It has the shape of a rough triangle, and is bounded on the east by the crests of the Nevada hills, and on the other two sides by two deep cuttings or valleys, fed by tributary streams of the Yuba, South Fork, and Middle Fork rivers. The auriferous gravel crops out along the courses of these valleys, but the alluvium is at a great height (more than 656 ft.) above the river courses. The thickness of the auriferous alluvium, measured on the incline of the table land, and along the valleys, is almost always more than 30 metres (98 ft.). The thickness of the gravel in the centre of the district is unknown. There is reason to believe that in some places there are not less than 100 metres (328 ft.) of gravel mingled with gold. The total area of the *placer*, according to tolerably correct maps, is 650 square kilometres (247 square miles).

If we now allow that this diluvial earth, impregnated with gold, has an average thickness of 30 metres or 98 ft. (the minimum measurement); and if we further suppose that the gravel contains 1 fr. 30 cents of gold per cubic metre (an average deduced from many undertakings), it will be seen that the total value of the gold contained in this single fragment of auriferous soil is not less than 25 millions of francs. This is an enormous and almost incredible sum. We must, however, remember that similar deposits have yielded 2 milliards 900 million francs of gold, within less than 12 years. All this mass of precious metal can be extracted. The means to effect this consist in the water for washing the gravel, and in the tunnels for carrying off the refuse. Such tunnels can be excavated as far as may be required, and with the necessary incline. This can be effected by starting with the adits from the sides of the valleys, and at the same time passing below the auriferous strata. The only thing now wanted would be a plentiful supply of water for washing the gold. As regards the *placer* we are now speaking of, this want has been fully supplied. A company of French miners, known under the name of the Eureka Lake Company, has carried out this extensive undertaking.

The Eureka Company collects the winter rains from the twenty eight lakes or high valleys of the Sierra-Nevada mountains. There are twelve dykes already constructed, thereby forming the same number of reservoirs of water. The canals that convey the waters and distribute them over the gold field are 337 kilometres long (209 miles). These conduits of water cross the mountain gorges by means of numerous aqueducts. A magnificent one, called the Magenta aqueduct, measures 1,900 ft. long, and has a height of 45 metres (147 ft.). The company already supplies 40 millions of cubic metres of water annually; but an exact gauging of the reservoirs shows a total supply of 480 millions of cubic metres. If we suppose a loss of one-third in evaporation, in standing still, &c., there remains a total of 320 millions of cubic metres for gold washing purposes. This quantity is about 100 times the annual consumption of the mine of San Juan alone, that we have already taken for an example. We can now suppose that the entire gold field, if fed by all the water of the Eureka Company, would produce one hundred times as much gold as the single mine of the San Juan. A total of sixty millions of francs' worth of gold per annum would thus be produced. According to the figures that have been given somewhat previously by M. Laur, it will be seen that the production of sixty millions could be continued for five years without exhausting the gold deposit. M. Laur has supposed that the mine of San Juan is only worked two hundred days in the year.

Such is the balance-sheet of one of the Californian mountain workings of auriferous gravel, and such is the future that these deposits open for the production of gold.

The alluvia we have examined are not the only gold mines of California. We have to show the importance of the *primary* auriferous deposits. A short description will suffice. The golden belt of California is traversed through its entire length by an unbroken bundle of large and small veins of quartz. This zone has a maximum breadth of about 12 kilometres (7½ miles); its length is at least 200 kilometres (124 miles). The quartz veins traverse all kinds of soil, and they extend to any depth. They sometimes crop up to the surface, and show their course for several leagues. The veins are formed of a hard and white rock, called rock crystal. They all contain gold. Sometimes the gold penetrates the entire depth of the seam, and in the form of a fine dust like flour; in other instances the gold is found in enormous nuggets of dazzling wealth. The quantity of gold contained in each cubic metre of rock is generally higher in the smaller than in the larger veins, and there is, generally, more gold at the surface. The degree of wealth is very changeable and uncertain; there is nothing to indicate to the miner the amount of the future produce of his labour. Some mines, still at work, give results varying from a maximum of 350f. to a minimum of 35f. worth of gold per ton. It is impossible to carry on an undertaking furnishing less than 38f. per ton of quartz. At Mariposa, in the Fremont Lode, a single blasting operation gave a block of quartz containing 375,000f. worth of gold. Such examples occur but seldom. It is difficult to give an average between results varying to such an extent. M. Laur thinks that he is not far from the truth in estimating the average at 16 or 18 dols. (about 18f.) per ton. There is thus nearly one hundred times as much gold in a ton of this mineral compared with the gravel of San Juan; but what a difference in the labour necessary to extract the metal!

In working the gold quartz it is necessary to blast the rock by means of gunpowder, and the mines are often filled with water. In order to pump out the water, and to wind up the minerals, steam-engines are required. On the gold quartz being brought to the light of day, the gold must be separated from the barren rock. In California, these expenses come to 33f. 70c. per ton, by the time the mineral is excavated. The ore has then to be conveyed from the mines to the stamping mills, and the carriage increases the expense by about 3f. 50c. per ton. At the works the gold quartz must be broken up and crushed to fine sand, by means of heavy cast-iron stampers, driven by a steam-engine, or a water wheel. The sand must then undergo the washing and amalgamating processes to extract the gold. The expenses of these further operations come up to about 17f. 80c. per ton, of mineral. A sum of 3f. per ton must be added to these special expenses; on account of the general outlay required in all undertakings of some importance. The total expenses thus came up to a sum of 60f. for the manipulation of one ton of quartz. M. Laur has given above 85f. per ton, as the average produce of this class of gold ore. The profits is thus only 25f. per ton; a very low sum for enterprizes of this description.

The gold quartz mines of California are not very attractive at present, but magnificent hopes were conceived of them at the beginning. This was in 1853; the river *placers* were then nearly exhausted. The crests of some quartz veins at Grass Valley, at Nevada, and at Mariposa, furnished very rich ores, and thus immediately attracted the attention of the miners. These men repeated that the gold was not to be found in extraneous situations, but rather in the depths of the ground; the real source of the treasures was in the bowels of the mountains. The rocks were at once attacked on all sides. Within less than three years a number of steam-engines from London and New York, amounting to 1,500-horse power, were set to crush the quartz of the Nevada mountains. The results were very disappointing; and a great number of the original companies got crushed under the heavy expenses. The entire plant of the ruined undertakings was then purchased under cost price by fresh companies, who were thus enabled to work with some profit. These undertakings are still carried on, but, in general, they work with some difficulty. They have to encounter two continually increasing obstacles—1, a diminution of the produce; and, 2, an increase of the expenses, as the excavations get deeper. It is possible that this state of things may improve, as the price of hand-labour will probably get lowered. The production could thus be kept up; but these quartz mines do not offer those immense prospective results afforded by the great extent of the *diluvial alluvia*. The working of the quartz mines struggles between the poorness of the quartz and the expenses of its manipulation. The outlay increases with the depth of the mine, while the amount of gold contained in the quartz proportionately diminishes. The production of the gold, day by day, narrowed between these two limits, will always be of comparatively secondary importance.

This information as to the goldquartz mines of California possesses a peculiar interest at the present time, as several companies are being formed in London to work the gold quartz found in Wales. The relative positions of England and California are evidently very different. The prices of labour, transport, steam power, and capital, are necessarily much lower with us than in California. As is well known, traces of old Roman gold workings have been discovered in Caermarthenshire, resembling the similar Roman remains often found in Transylvania. M. Laur, as we have seen, lays great stress on the fact that the gold quartz always diminishes in wealth in a direct ratio to the depth from the surface. It is probable that the same phenomenon will be observed in the Welsh quartz rocks. It is a matter of history, recorded in "Cæsar's Commentaries," that the Romans invaded Britain for the sake of her mineral wealth. Even now, the Cornish miners sometimes find small particles of gold in the tin workings. The Black Prince was aided in his French wars by a gold mine at Combmartin, in Devonshire. The gold of Wicklow, in Ireland, is another instance of the precious metal being found in the British Isles. Just as the Californian rivers became impregnated with gold through the undisturbed and prolonged action of water currents on the gold-bearing rocks, so, in the same way, it is possible that the British rivers contained at one time some amount of gold dust. It will probably take thousands of years before Californian rivers return to their pristine state in 1848. We can thus fully understand that the ancient British rivers may have contained a certain amount of gold, of which but few traces are now to be found.

There are several other kinds of gold-bearing rocks in California, besides the auriferous quartz rock. M. Laur observed several mountains of shist impregnated with gold through their entire mass. These deposits are almost unknown, and have not been excavated. It is impossible to precisely determine their importance.

An important conclusion can at once be drawn from the facts as stated above. California will never cease to produce large quantities of gold. The amount extracted at present, 230 to 250 millions of francs, will probably increase; and in no case will the production diminish before centuries have elapsed. The influence in the money market of such a quantity of gold, extracted at a price so much below market value, offers a problem well worthy the attention of the political economist. This is more especially the case if we take into account the profitable influence of the new methods of working on the production of the gold existing in other parts of the world besides California. It is at present pretty certain that *diluvial auriferous* alluvia exist throughout the entire chain of the Ural mountains, from Ekaterinenburg to the Frozen Sea, and through the whole of the great hilly chain separating Southern Siberia from the Chinese Empire; from the high table-lands of the Kirghez up to the sources of the River Amur. Gold is scattered throughout the entire surface of this territory; a length of more than 4,500 kilometres (2,790 miles.) This immense gold field has been worked at a great number of places, and gold has everywhere been found. The eminent geologist, Sir R. Murchison, has established, in his reports, that the auriferous alluvia of these regions afford an average of five millionths of their weight in gold, or about 5 grammes (77 grains) of metal per ton of sand. Further, that the working expenses are so high, that no profit is afforded if this proportion gets lower than two millionths, or two grammes of gold (30·8 grains) per 1,000 kilogrammes (19½ cwt.) of sand. These figures prove that 400 grammes (12·8 oz. troy) of gold are expended in extracting one kilogramme (2·2 lbs. avoirdupois.)

Let us now suppose that, other things being equal, the new methods invented at the *placers* of the Sierra-Nevada could be applied on the Altai valleys. The alluvia producing only two grammes (30·8 grains) per ton, at present abandoned as too poor, could be immediately worked at a great profit; for the Californian method in its highest development can elaborate, without loss, minerals containing only five grammes (77 grains) of gold to 100 tons of sand. Those gold soils, the contents of which are between these two terms: two grammes (30·8 grains) of gold to 1,000 kilogrammes (19½ cwt.), and five grammes (77 grains) of gold to 100,000 kilogrammes (nearly 100 tons), at present abandoned, could be at once worked with profit. There is not the slightest doubt that this gold bearing mineral exists in very large quantities, and that the amount of gold to be extracted is very great. The present workings produce five grammes of gold per 1,000 kilogrammes of washed-out sand; but instead of expending in this work two grammes of the precious metal, the Californian methods would only expend five centigrammes (0·77 grains.) The kilogramme (2·2 lbs. avoirdupois) of gold, instead of costing 400 grammes (12·84 oz. troy), would only cost ten grammes (154·34 grains), an expenditure forty times less.

We might multiply these instances, and we could compare the gold washing of the Rhine, of the Brazils, of Chili, and of Peru, with the working by the *sluice*, and the Californian method of excavating the soil by means of water jets. We should then see that the employment of these new processes would doubly increase the production, first, by increasing the area of the gold fields workable with profit; and secondly, by diminishing the working expenses. It can thus be asserted that in future gold will be produced cheaper and in greater abundance than formerly, in all the gold mines in the world. No term can be assigned to the amount of this production, on account of the infinite variety of the gold deposits, nor would it be possible to state the lowest converging point of the price and value of the *still* precious metal.

Such has been the part played by California in the production of gold. It has not merely produced the metal in large quantities, but this country has also revealed to the whole world the best methods for cultivating gold. Through an accidental discovery, California suddenly burst upon the scene, and almost immediately produced nearly as much gold as all the rest of the world put together. (Before 1848, all the gold mines of Europe, Africa, and America together, produced 247 millions of francs of gold per annum. The production of California alone came up to 228 millions in the year 1851.)

California has shown that gold, like commoner metals, is to be found extended over large surfaces, within the rocks, or spread over their exterior, and that gold has been brought to the light of day by similar geographical revolutions to those that have produced the mines of lead and copper; worked for so many centuries in the old world. The facts observed on the Sierra-Nevada, of California, led one to believe that gold is perhaps more abundant on the surface of the earth than had been previously supposed. It is well known that an attentive examination of the California hills led the miner Hargreaves to conclude that gold was also to be found in the mountains of New South Wales; at present the California of England.

It can be said that California has vulgarized gold, and it is probable that this country has thereby given an impetus to the great manufacturing activity in Western Europe that has marked the last two years. Will California ever effect the same for silver as for gold? M. Laur is inclined to believe that this will be the case. Not that the country contains the silver itself, as was once erroneously supposed, but because California can supply, in great abundance, another metal, very expensive up to the present. This is mercury, an indispensable agent in all the silver mines of the new world. In the mountains on the coast, near San Francisco, there exist extensive veins of sulphuret of mercury. These veins have been worked for a few years only, and they produce already more than 1,340,000 kilogrammes (nearly 132,000 tons) of quicksilver. This is as much as the produce of all the other mines of the world put together. Mercury was formerly sold in San Francisco at 7f. to 8f. the kilogramme; it will soon be only worth 3f. or 4f. There is no doubt that this great lowering in the price of mercury will, ultimately, also cause a great reduction in the price of silver.

What will be the ultimate results of this immense influx of the precious metals on the money market? These are great and important inquiries. The continued and rapid increase in the production of gold will of itself answer these questions within no lengthened period of time.

H.

GUN SHIELD AND GREAT GUN EXPERIMENTS AT SHOEBURYNESS.

(From our Special Reporter.)

Tuesday last was the first day of the experimental season at Shoeburyness. There was a numerous gathering of members of the Ordnance Select Committee and Iron Plate Committee, and military and naval officers. Only a limited number of civilians were present; but Royalty was not wanting, Prince Louis of Hesse and Prince Arthur being on the ground. The proceedings, which commenced at 10.30, were not terminated till four o'clock.

The experiments on this occasion had a double interest, their object being to test the resisting force of a gun shield, constructed under the direction of Captain Inglis, of the Royal Engineers, and the destructive powers of the guns of three eminent artillerists—Armstrong, Whitworth, and Lynall Thomas. The nature and object of the gun shield not being generally understood, some description of it may be acceptable to our readers.

As we pointed out in a recent article, the introduction of iron-clads into naval warfare, makes it compulsory to protect land batteries for coast and harbour defences with iron casing. An armour-plated vessel carrying a few heavy guns could range alongside a battery unprotected with iron, and damage it seriously without receiving any material injury itself. In the attack of the "Montauk," turret gunboat, armed with only two Dahlgreen guns, on a fort commanding the entrance to the port of Savannah, the vessel fired 84 rounds at point-blank range, and was struck by 46 heavy shot, receiving little injury, but also doing no material damage to the land batteries, because, as it is stated, they were iron-plated. Our Government has been fully sensible to the necessity of this kind of protection for our maritime forts, and intends to apply it without delay to those on the most vulnerable points of our coast. They are only waiting for the Ordnance officials to determine which is the best system of armour-plating for the purpose, and, in that respect, there is as much perplexity in the professional and scientific mind as there is with reference to iron-clads. In this matter the Ordnance is acting with laudable caution, being apparently anxious not to fall into the error committed by the Admiralty, of adopting and expending large sums on a system which has not been tested. The War Department has been for some time engaged in the construction of experimental gun shields, some of which were tried last year, with doubtful results. The one tested on Tuesday was regarded by the officials as a combination of the best points of those previously tried. Its chief feature is massive strength, resulting from great thickness of solid metal, obtained by iron planks placed across each other. These planks are 5, 6, 7, and 8 in. in thickness, and are about 20 in. in width, those in the front being 8 ft. long in a vertical direction, and those behind 11 ft. long in a horizontal direction, corresponding to the dimensions of the shield, which are 11 ft. in width and 8 ft. in height, with an embrasure in the middle, 3 ft. 6 in. by 2 ft. 4 in. Strong iron struts, projecting behind at each end, and connected with vertical and horizontal iron bars with a section of 9 by 5 in., together with foundation plates, form a framing, which supports the structure, the whole being fastened together by 3-inch through bolts, which pass through holes perforated in the planks and supporting bars. The heads of the bolts being conical, hold the plates in front, and are screwed up behind with nuts against iron washers, some of which are combined with india-rubber, some with plaited wire, and others with lead. Some washers are all iron, and a few of the bolts are rivetted. These different kinds of washers and bolts represent two systems of resistance, the elastic and the rigid, the efficacy of which was put to the proof by the powerful projectiles fired at the shield. The entire structure was, indeed, severely tested; but before we describe its condition at the close of the experiments, we will give an account of the performance of the guns.

Four guns were made use of—the Whitworth 7½-inch hexagonal bore, the Armstrong 9-inch smooth bore, the Armstrong 10½-inch rifled on his shunt principle, and Lynall Thomas's rib-rifled 7-inch bore. We purposely name the guns by their bore, because it is the true measure of their force, as it regulates the charge; and we wish to put an end to the objectionable practice of expressing the force of a gun by the weight of the projectile, which, in the case of elongated shot, conveys an erroneous conception of the real character of the arm. This has given rise to much confusion, and has even been the means of misrepresentation in puffing the Armstrongs into notice. The old-fashioned smooth-bore nomenclature is right. The weight of a spherical shot is regulated by its diameter, which corresponds with the bore of the gun. But an 8-inch rifled breech-loader, which is only a 70-pounder, does not become a 110-pounder or a 200-pounder by being loaded with a bolt of the latter weights; nor is a 10½-inch shunt muzzle loader, which would only carry a 150 lb. round shot converted into a 300-pounder, by increasing the length of the projectile. Whitworth's gun, which should rank as a 70-pounder, is improperly called a 120-pounder. When a 68-pounder is double shotted, it does not become a 136-pounder. If this deceptive mode of measuring the force of guns by the weight of metal discharged from the muzzle, is to be followed in experimental practice, we shall, when a comparative trial of smashing effect is to come off, put in a claim on behalf of the old naval 68-pounder, that it be fired double-shotted, with an increased charge proportioned to the additional quantity of gunpowder used in an Armstrong or a Whitworth when a demonstration is to be made. The fact is, that a great delusion has been practised on the minds of the uninitiated by parading high figures as the weights of rifled bolts. Increase of weight sacrifices velocity; and as projectile force is a compound of weight multiplied by the square of velocity, the explosive force remaining the same, the useful effect, the real work, of the 200-pounder Armstrong shot is less than that of the 100-pounder, and the effect of the 300-pounder less than that of the 150-pounder. The experiments at Shoeburyness have proved that fact; it is well known to Sir William; and nevertheless, to this day his 100 and 150-pounder guns are boastingly designated as 200 and 300-pounders. There was a time when he thought he should establish a reputation for his artillery, by firing elongated projectiles of great weight, but the Warrior-target demolished that thing. The 200 lb. shot fired from the 100-pounder were a complete failure. They had no penetrating force—they produced a slight indentation, and fell exhausted at the foot of the target, unbroken, except at the nozzle of the cone, not having force enough to destroy themselves, although made of cast iron.

Although the experiments extended over so long a time, seven shots only were fired at the Inglis target. The intervals between them were necessarily long, to give time to the officials to examine and take notes of the results. As the Ordnance and the Iron Plate Committee were mutually interested in the attack and defence, a double set of officers were engaged in observing the results of every shot, and during the early part of the morning there was much delay arising from vessels passing within the range. We understood last year that this obstruction to the practice at Shoeburyness was removed by an Act giving the War Department jurisdiction over the navigation along this coast, a certain distance out to sea. The Act being passed, the proper authorities should take care when experiments are to be made to adopt and give publicity to a signal to warn off the barges and small coasters which use this passage.

The first shot was fired from the Whitworth hexagonal bored gun—the same gun which drove flat-headed steel shot and shell through the "Warrior's" armour plates. The projectile was of the same description as the solid bolts fired on that occasion, weighed 148 lb., was made of homogeneous iron, and fired with 25 lb. of gunpowder, the impact velocity being 1240. To render our description of the effect intelligible, we will here explain that the outer face of the shield being covered with the vertical iron planks in six divisions, each 8 ft. high, and about 20 in. wide, we will refer to them as Nos. 1 to 6, reckoning from the left front, No. 3 containing the embrasure in the middle. This first shot struck No. 5, the second plate to the right of the embrasure, extending a little over the joint to No. 4. The effect was tremendous, and is best described as an awful smash. The shape of the area of impact was curious; it had no approach to the circular form, but was irregular and apparently splashed, as if a mass of clay had been dashed against the plates. The surface thus covered measured about 16 inches in every direction; its size and irregularity prove that the projectile, from the nature of the material, did all its work on the plates. It did not, like cast-iron shot, break up at the moment of impact into fragments, which recoil, but the whole momentum of the entire mass fell on the plates. The actual indentation it was impossible to measure: a large piece of the projectile was imbedded in No. 5 plate. The damaging effects behind the shield told the force of the shock; the massive frame-bar at the bottom, with 12 in. of solid iron intervening between it and the impact, was dislodged, and parts of the supporting strut were separated from each other. One bolt, which afterwards broke, was supposed to have been cracked by this shot. In front a crack ran across the impact surface; and the plate to the left (No. 4), which is 8 inches thick, and was only grazed by the shot, was broken in two about three feet above the line of the blow.

The second experiment was with Armstrong's 9-inch smooth-bore, from which a spherical shot weighing 100 lb. was fired with a charge of 25 lb. and a velocity of 1,470 ft. per second at the moment of striking. This was the highest velocity attained in this day's practice, and confirms the superiority of smooth-bores, already established by the 68-pounder, over rifled guns at short range, proving that at close quarters the former are more formidable than the latter. The most experienced naval officers are of opinion that the attention of artillerists should be directed to the improvement of the smooth-bore as a more effective means of producing a perfect naval gun than any system of rifling. Has Sir William Armstrong become a convert to this opinion? Are we to take the introduction of this 100-pounder as an indication that he is not so wedded to the rifled principle as he was? If so, Mr. Whitworth must look to his laurels; for if any dependence is to be placed on the theory of momentum in projectiles, the new Armstrong is a formidable competitor. It has, with 25 lb. of powder, its service charge being 35 lb., produced a result equal to the maximum effect of the hexagon 148-pounder. The former, with its service charge, would, probably, without any risk, produce a velocity exceeding 1,600 ft., whilst the charge of the latter could not be safely augmented. But things should be called by their right names. The Armstrong is a 9-inch, the Whitworth a 7-inch bore; the first carries a heavier charge, and ought to be of greater force. The second shot did extensive damage to the shield. If the effect of impact on the surface was not so great as that of the first shot, the difference is to be ascribed to the inferiority of the metal of which the former was composed. By breaking into fragments it did not do all its work; whilst the success of Mr. Whitworth on this as on former occasions, is largely due to the very superior quality of the iron of which his projectiles are made. The damage, however, to the target was extensive. The 8-inch plate No. 4, was cracked across at the line of impact. The 5-inch plate at the back was broken in two; a frame bar, 9 by 5 in., supporting these two plates behind, was bent in about 2 in.; a 3-inch bolt was broken off at the nut, and the joints of the frame opened ¼ to ½ an inch at several places. The third shot, weighing 230 lb., was fired with a charge of 45lb. from Armstrong's 10½-inch rifled shunt. This gun is called anything. from a 150 to a 300-pounder. The plate struck, No. 6, was 6 inches thick, the third to the right of the embrasure. The damage done, although the projectile and the charge were so heavy, was by no means equal to that resulting from the two first shots. Still it shook the frame bars and strut terribly, separating the parts 1 to 2 in. and driving the foot of the latter out of its place. The maximum effect of this gun would, no doubt, be obtained with a hollow shot weighing 150 to 170 lb. and a charge of 50 lb.; but the question is, will the peculiar rifling bear so heavy a charge?

The Lynall Thomas rib-rifled 7-in. gun discharged the fourth shot, which was of wrought iron and weighed 150 lb., with a charge of 25 lb. and a velocity of 1,150. Plate No. 1, the outer one on the left, was struck about the middle vertically and close to the joint of plate No. 2, to the right. The indentation was round, about 7 in. in diameter and 2 inches in depth. The effect on the plates was more damaging than that of any preceding shot, two plates being cracked across their entire width toward the top, in a continuous zig-zag, from the embrasure to the outside of the shield through a bolt-hole a few inches above the impact, and one plate broken in two at the bottom. The strut and frame at the back were considerably shaken, and a bolt destroyed.

No. 5 shot was a repetition of No. 1—namely, a Whitworth 150-pounder, from the same gun, with a charge of 25 lb. Although it touched the ground and ricochetted a few yards in front of the target, it gave proof that its destructive force was little impaired. It struck a small plate, 24 in. by 21 in. and 8 in. thick, under the embrasure, this plate being backed with a 5 in. plate, which was supported behind by a bar 5 in.; thick by 9 in. wide. The plates which had been in close contact were separated ¾ to 1 in. and the bar was bent outwards 2½ in.; two bolts were broken, one being torn out of an adjoining plate, apparently by the sudden jerk of the bent bar, and hurled ten or twelve feet behind into a bank of earth. The lead washers to some of the bolts, ¼ to ½ an inch in thickness, were by the immense force squeezed to the substance of a thin card.

No. 6 was a second trial of the powers of the 10½-in. Armstrong, loaded this time with a 300 lb. cast-iron shot and 45 lb. of powder. This projectile hit the joints of plates 4 and 5 a little to the right of the embrasure, a few inches above the wide-spread indent of the first Whitworth, and partly on plate No. 4, of which the lower part had been cracked by the Armstrong shot, No. 2; this plate, although 8 in. thick, was split in two at the upper part. The whole structure of the shield was shaken by this heavy blow so near the top.

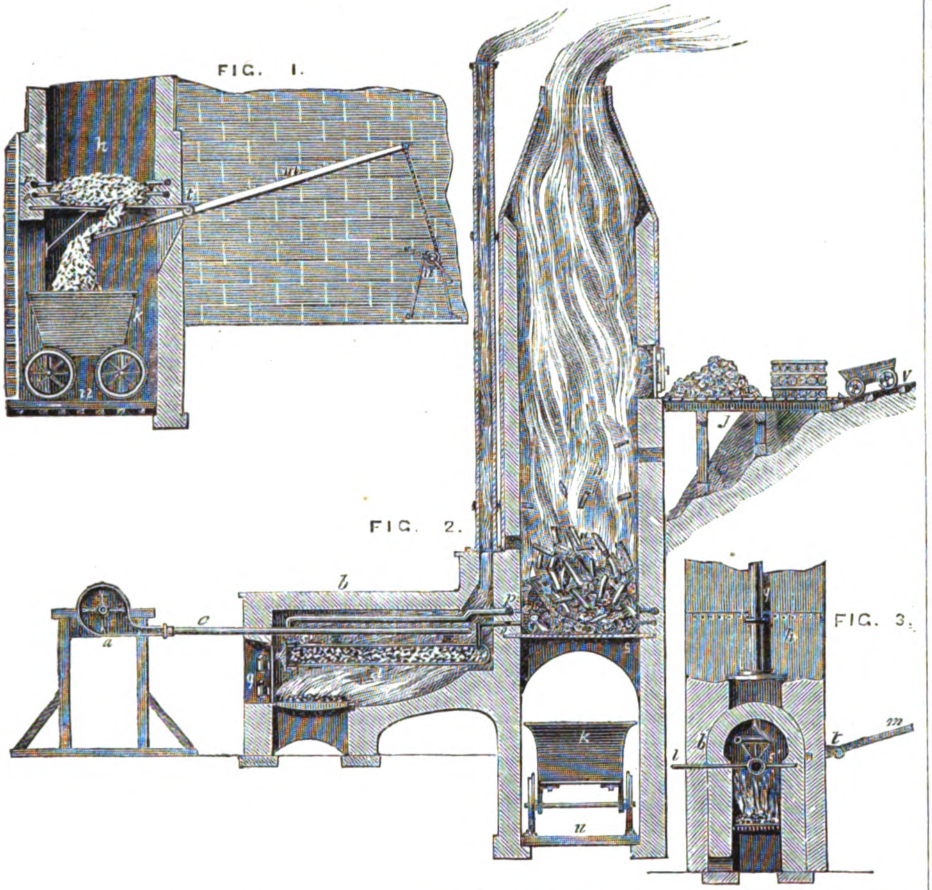
The last gun fired was the Lynall Thomas, which ended the experiments and its own existence by bursting with a tremendous crash. The shot missed the target and sped its way seawards. This was a sensation event. Many lookers on, who from the splinter proofs kept their eye on the gun, saw a black mass spring into the air through the canopy of smoke. The numerous groups which, after every shot had run a race at double quick to examine the target in a somewhat amusing fashion, rushed simultaneously at full speed to the battery, where a scene of havoc was exhibited. The massive tube, with the breech-end blown away, and the shrunk ring to which the trunnions were forged, burst asunder, lay prostrate on the ground, the carriage having been blown into fragments which lay scattered over the field. The mass of iron which had been seen high in air was found at a distance of 150 yards. The fracture of the breech showed the following dimensions—bore, 7 in.; inner steel tube, 1½ inch, and iron breech, 8 in. in thickness; making a total diameter of 26 in., without the outer shrunk ring or hoop, which was 13 in. wide by 3 in. thick. In an article on ordnance a few weeks ago, we pointed out that the peculiar kind of rifling of this gun made it probable that the action of the grooved projectile on the side of the rib, cut in relief on the bore, would show the strain of the force so much on the rib that there would be danger of bursting.

Mr. Lynall Thomas attributes the accident to the fact of the steel tube which carries the rifling being too much cut away. On the ground, it was stated that this work was done at Elswick. A larger gun on the same principle is being manufactured at Woolwich under the careful superintendence of Mr. Anderson. Mr. Thomas is confident of its success, but we fear the mode of rifling is a source of weakness which no care can overcome.

BLISS'S IMPROVED FURNACE.

THE annexed engravings represent an arrangement of apparatus for heating ores and generating steam, recently patented by Mr. W. Bliss, of Chipping Norton, which he describes as follows:—The blast furnace is closed at its lower end by a valve or slide, so that after the process of heating or calcining the quartz or ores the contents of the furnace may be discharged through an opening in the bottom of the furnace, which is closed by a valve or slide during the heating or calcining process. At the lower part of the blast furnace there is a hollow space all round, into which air, and also the gases obtained from decomposed steam, are forced during the process of heating or calcining the quartz or ores. A steam boiler is employed in connection with the blast furnace, by the fire used for heating which a retort is also heated, and it is found convenient to arrange this retort so that it may form the bridge across the end of the boiler furnace; but the retort may be otherwise arranged and heated. By means of a fan or other suitable blowing apparatus air is forced into the hollow space at the lower part of the furnace, and passes through several openings from such chamber into the lower part of the blast furnace, and it is preferred that the air thus forced into the blast furnace should be heated in its passage from the blowing apparatus to the furnace by causing it to pass through a pipe or pipes, or passages, heated by the fire of the boiler furnace, but the heating of the air may be otherwise accomplished. In the retort charcoal is placed, and steam from the boiler is caused to pass through and amongst such charcoal and from the retort. The gases, and any steam which may not be decomposed, pass into the space at the lower part of the blast furnace, and thence through the passages into the blast furnace. In working with this arrangement of apparatus a quantity of fuel is placed at the bottom of the blast furnace, and also the quartz or other ores requiring a like process. Air and gases are forced into the blast furnace, by which a very high degree of heat is obtained; after a time it is preferred to stop the introduction of the air blast, and to continue the application of the gases till the process is com-

BLISS'S IMPROVED FURNACE.



plete. The air and gas pipes are protected by fire-clay or bricks when using the apparatus for generating steam to be applied to work steam-engines, and where no heating or calcining furnace is used, the gases obtained from the steam are used in the steam-boiler furnace.

SOCIETY OF ENGINEERS.

March 2nd, 1863.

ON THE RELATION BETWEEN THE SAFE LOAD AND THE STRENGTH OF IRON.

By Zerah Colburn, Esq., C.E.

A great number of experiments have been made by many experimenters, to ascertain the ultimate resistance of iron to tension and compression, and its strength has thus been determined with perhaps as much precision as is possible in the case of a material presenting almost constant variations of quality. Every engineer is now aware that, as an average result, the tensile strength of cast iron may be taken as about 8 tons per square inch, and its crushing strength at 48 tons. Wrought iron of fair quality will bear from 26 tons per square inch in tension, while its crushing strength is variously stated at from 12 or 15 tons per square inch up to 28½ tons, the last named being given by Mr. Mallet as the result of experiments upon large hammered bars, which bore but from 23 tons to 24 tons in tension.

When, however, we come to the question of safe-working strength, much difference of opinion exists among engineers, the permanent supporting power of iron being variously estimated at 4-10ths down to 1-10th of its breaking strength. Thus when, some fifteen years ago, a Royal commission sat to inquire into the application of iron to railway structures, the late Mr Glynn, in his evidence, recommended that a cast-iron bridge should never be loaded beyond one-tenth of its ultimate strength. The late Mr. Stephenson, with several other engineers, thought a ratio of one-sixth sufficient, while the late Mr. Brunel was satisfied with a ratio of from two-fifths to one-third; or, in other words, if a girder would just bear 100 tons of distributed load, he would put from 33 tons to 40 tons upon it, where Mr. Stephenson would allow not more than 17 tons, and Mr. Glynn only 10 tons.

Were we now to have another commission entrusted with the same inquiry, it is not unlikely that as great a difference of opinion would be found still existing. For there is no acknowledged natural principle upon which the safe load of iron has yet been determined, and in the absence or oversight of such a principle each engineer must be governed by his own judgment of what is safe and prudent. It is true that the authority of the Board of Trade has been so far exercised in this matter as to have limited engineers, in the design of wrought-iron railway bridges, to maximum tensile strains of 5 tons per square inch; and although it is commonly believed that with wrought iron a compressive strain of from 4 tons to 4½ tons corresponds to a tensile strain of 5 tons, the Board of Trade impose the same limit of strain for both the top and bottom chords of a wrought-iron girder. The limit of 5 tons per square inch, it is hardly necessary to say, is an entirely arbitrary one, nor is it modified according to the quality of the iron and workmanship in a structure. Thus, in girder bridges, plate iron is used, of which the breaking strength is occasionally not more than 18 tons per square inch. In punching the rivet holes, however, and irrespective of the loss of the metal actually punched out, the solid iron remaining between the holes is injured, so much so that, in a series of experiments made many years ago by Mr. Fairbairn, the mean tensile strength of seven specimens was reduced from 52,486 lb. per square inch before punching to 41,590 lb. per square inch of solid iron left between the holes after punching—more than 20 per cent. of the strength of the iron being destroyed by punching, a loss distinct from that of the metal actually punched out. Drilled rivet holes, it is satisfactory to know, are now being adopted in the best class of bridge work; but in bridges already erected and containing plates occasionally no stronger than 18 tons per square inch before punching, the loss of strength ascertained by Mr. Fairbairn would diminish this to about 14⅓ tons for the net section of metal between the rivet holes. On the other hand, the best suspension-bridge links have a strength of from 26 tons to 28 tons per square inch of section, and yet the Board of Trade inspecting officers would not probably depart from the arbitary limit of a maximum strain of 5 tons in either case. As far, therefore, as is necessary to meet the requirements of the authorities, good iron and sound workmanship go for little or nothing: and not only does this remark apply to the inference of the Board of Trade, but in the case of Chelsea Suspension-bridge, the chains of which are believed to have a tensile strength of upwards of 25 tons per square inch, two of the leading members of our profession have declared that structure to be unsafe until it shall have been so strengthened that the greatest load which the heaviest traffic is likely to bring upon it shall not exceed 5 tons per square inch of the sectional area of the chains. The highest authorities, we are justified in supposing, would, at the same time, be satisfied with the same maximum strain in the chords of a plate girder bridge, even if the actual breaking strength of the solid iron between the rivet holes did not, as we have reason to believe it often does not, exceed 15 tons, or three-fifths that of the links of Chelsea Bridge.

While some of the conditions of elastic action are now under consideration, it appears desirable to define, as nearly as may be, what elasticity really is. We are all familiar enough with its manifestations, as in a watch spring, an air cushion, or a bit of india-rubber, but we seldom inquire to what condition of matter these manifestations are to be attributed. When, however, we regard matter of any kind as a collection of distinct molecules or atoms, between which the force of attraction is always predominant in solids, and the force of repulsion in gases, we have no difficulty in perceiving that any alteration in the amount of either of these forces, acting within a body, must produce a corresponding change in the distance between its atoms, and in this very change of distance we have the whole phenomenon of elasticity. Elasticity is not a force, but the result of the antagonism of two opposite forces: an antagonism in which either force continues to act through a certain range or distance—a range differing greatly in different materials—before being completely overcome by the opposite force. Under the influence only of attraction the particles of all matter would cohere, and without repulsion there could be only solid bodies in nature, for the existence of liquids and gases would then be impossible. The repulsive force appears to be the force of heat, to which physical repulsion may be generally traced. Under the influence of heat alone, and without attraction, there could be neither cohesion nor liquidity, and all substances could exist only in the gaseous state. We shall soon be able to trace the bearing which these distinctions have upon the elasticity of iron. At present we have only to bear in mind that there is reasonable physical evidence to show that the atoms of matter, so far as we can comprehend their existence, are never in actual contact with each other, even in solid bodies. Iron, as we know, is a comparatively porous material, since air and water may be readily forced through it under moderate pressures. Mercury, it is well known, will rapidly insinuate itself between the pores of an apparently solid body, for gold immersed in mercury will acquire the condition of an amalgam, and will crumble to powder. We know, furthermore, that the particles of most, if not all, solid bodies may be so far separated by heat as to convert them into liquids, and it is quite reasonable to suppose that, with an additional degree of heat, or repulsive force, all these liquified solids might, like mercury, and even melted gold, be converted into vapours. Now, any force applied after the manner of tension in a bar of iron, thus tending to separate the particles, in opposition to their cohesion or force of mutual attraction, may be considered to act in the same manner as the repulsive force of heat. The point at which rupture will take place will evidently be where the particles are so far separated that the cohesive force is less than the tensile strain, but there is good ground for supposing that, even after rupture, the atoms of the iron would again cohere could they be again brought to within their original distance from each other. This, of course, would be impossible if we attempted merely to place the two fractured surfaces in contact. In the case, however, of two clean surfaces of lead, we may readily bring them so closely together as to restore cohesion, and, in the same way iron journals running in steel bearings occasionally become welded to them when the pressure is too great for ordinary work. In thus bringing two bodies within the range of cohesive force, we must remember that it is the ultimate atoms which cohere, and that the finest perceptible particle of matter may really consist of myriads of almost infinitely smaller atoms. In all welding we first employ a degree of heat sufficient to overcome so much of the cohesive force between the atoms of the iron as to allow of sufficient motion among themselves to bring all, or most of the atoms forming one surface, within cohesive range of those forming the opposite surface. Two cast-iron surfaces are readily welded together by running melted iron between them. Without heat the two surfaces, however well-finished, would touch only at a great number of separate points, although there would be considerable cohesion even then, as every one knows who has brought two carefully scraped surfaces of iron, or two sheets of plate-glass together; and although a part of the apparent cohesion is due to the pressure of the atmosphere, there would really be some cohesion in a vacuum. It is only from the fact that the atoms of matter will always cohere when once brought sufficiently near together, that we are enabled to make bricks and all articles of earthenware. Soluble bodies, like clay or salt, cohere after solution and evaporation, simply because their atoms, having been first separated by the liquid solvent, are again left within cohesive range on the evaporation of that solvent. Bricks, but for the waste of fuel in burning them, might be made from the most dilute solution of clay, and the final baking is only necessary in order to so completely expel the moisture as to bring the clay atoms within the range of cohesion, but their own character is in no respect altered. Iron, were it possible to dissolve it without combining it with nitrogen, oxygen, sulphur, or other matters, would again return to its ordinary granular state, and would recover its cohesion, on the evaporation of the solvent. Great pressure, too, will effect cohesion in the case of substances naturally having none at all. Thus, in experiments made with the ballistic pendulum to ascertain the velocity of cannon shot, the sand packing against which the shot is fired is often converted into sandstone of considerable strength.

From the illustrations given, the elasticity of solids appears to be no more than the range or play of the attractive and repulsive forces of matter, as variably exerted, but within the limits of rupture or crushing. Thus elasticity is the same in kind whether the repulsive or separating force be externally applied, or whether it be that of heat acting between the molecules of the body. If a bar of good wrought iron be stretched to the 1-1000th part of its length, corresponding, say, to a strain of 10 tons per square inch, its elasticity will be fully excited or nearly so, and it will not support a much greater strain without taking a permanent set. It is true that, if the same bar of iron, when not under strain, be heated to from 150 to 200 deg. above its normal temperature, it will also elongate by 1-1000th part of its length, and that without injury. But if this elongation takes place under a compressive strain, or, if the iron, first raised in temperature by 200 deg. and thereby elongated, be attached to two fixed points, and thus, while cooling, be made to contract under strain, it will be found that an elongation of not far from 1-1000th of the original length of the bar is the most that can be borne without injury, even when that elongation is due to heat alone. But if the iron be first heated sufficiently to soften it, as railway tyres and gun hoops are heated, the particles will be re-arranged and, within certain limits without injury; but after the metal has once cooled below the temperature at which the particles have the mobility necessary for this rearrangement, any further contraction around an unyielding object will be attended with permanent and, there is reason to believe, injurious strain. Even in setting railway tyres, it is believed to be best to put them on cold, and under graduated pressure; and in the case of gun hoops, Captain Blakely and Mr. Mallet, who appear to be entitled to the credit of the modern system of the ringed construction of artillery, have always insisted upon the importance of a definite degree of shrinkage of each ring, so that the consequent strain shall not exceed the elastic limit of the material. Sir William Armstrong has stated that he does not consider any especial accuracy essential in the distribution of the strains imparted by shrinking his gun hoops upon each other; but it may be questioned how far the failures of so many of the Armstrong guns have been due to neglect in this respect.

It would be interesting to know the precise manner in which a separating strain acts upon the molecules of iron, or rather to know the successive positions of the atoms during the application of the strain. We are, however, without any positive knowledge of the positions which the atoms assume in solidification and under subsequent forging; but the multifarious forms in which all atoms visibly crystallize serve to show us that they cannot all be at equal distances from each other throughout the whole body. If they were, the arrangement would be that of cannon balls in a triangular pyramidal pile. Could we visibly represent the atoms as occupying the angles of an infinite number of equilaterial triangles, we should understand that a linear strain acting to separate any two of the atoms would, at the same time, draw a third atom, if not a number of atoms partly between them. And when, from this intrusion, the repulsive force, or heat, always enveloping the intruding atom, had once overpowered the attractive or cohesive force existing between the two atoms thus strained apart, these would, in turn, cohere anew to the atom which had been drawn in between them, and thus we should have a permanent rearrangement of the atoms, or, in other words, a permanent set, with permanent elongation in one direction, and permanent contraction in a plane at right angles thereto. That the atoms are thus drawn into parallel rows of straight lines, in many kinds of iron at least, seems evident from the appearance of fracture, which presents stringy collections of particles forming what is commonly called fibre, although there is great reason for doubting that anything like fibre existed in the iron before it was broken. Mr. Kirkaldy's recent extensive experiments appear to show, as many others have shown, that iron may be made to break short or to break with an appearance of fibre, just according as it is broken with a sudden blow or a gradual pull. Something like fibre may be imparted, on a coarse scale, by repeated rolling or in wire-drawing; but it is more probable that masses of atoms are thus drawn into strings than that any fibre is really imparted to the atomic arrangement itself.

It is commonly held that, within certain limits of strain, iron is perfectly elastic. No matter how often it may be stretched or deflected, up to a certain point, the general belief is that it will come back to its original form every time the load is taken off. There are high authorities, however, who maintain that iron takes a permanent set under even very moderate strains. If we are to understand that the set is exceedingly small, this may be true. The late Mr. Hodgkinson, for example, remarked, on the 381st page of his "Experimental Researches," that two cast-iron beams took each a permanent set with weights respectively equal to 1-57th and 1-80th of the breaking weight. In a discussion at the Institution of Civil Engineers, a Mr. Dines mentioned that he had tested upwards of 8,000 cast-iron girders for the late Thomas Cubitt, and that he found it hardly possible to apply a weight so small as not to produce some permanent set, 1-20th of the breaking weight producing a perceptible set. In the experiments of the Iron Commission at Portsmouth a bar of annealed wrought iron 50 ft. long was said to have taken a perceptible set with a weight of less than 1¼ tons per square inch. After this weight had been doubled, however, the set was still only perceptible; and notwithstanding that the elasticity of annealed iron is known to be inferior to that of unannealed bars, the whole set of the 50ft. bar was but the 1-250th part of one inch, after a strain of 8⅓ tons per square inch had been borne; and the set was but the 1-20th of an inch in 50ft. after a strain of 11·9 tons per square inch. Mr. Edwin Clark has experimented on a wrought-iron bar 10ft. long and 1in. square. Under a strain of 3 tons per square inch he gives a permanent set of nearly the 1-4000th part of an inch in 10ft. With 8 tons the permanent set is given as about the 1-1280th of an inch in 10ft., and it was not until a strain of 13 tons per square inch had been applied that a set of 1-32nd of an inch in 10ft. became apparent. With such exceedingly minute measurements, we may, perhaps, doubt if there was really any permanent set at all, with strains under 9 or 10 tons per square inch. An increase of temperature in the bar of perhaps a single degree, while the measurements were being made, would more than account for some of the reported sets, even under considerable strains. Thus Mr. Edwin Clark gives the permanent set of his bar, after a strain of 8 tons per square inch, as the 1-153,846th part of its length, and this is almost exactly what the extension of the bar would have been had its temperature been raised but a single degree between the observations. Iron is heated in the very act of straining it, and a sudden breaking strain will generally leave the broken ends too hot to be handled. Such a slight apparent extension might also have occurred while the shackles by which the bar was strained were coming to their bearings. But even if such a microscopic permanent set really existed, it is one of which no engineer would take the slighest serious notice as affecting the strength of the bar in which it was observed. With the means of measurement commonly employed by engineers ordinary wrought iron is seldom permanently stretched until after it has borne strains of upwards of 8 tons per square inch. In seven experiments by Professor Barlow, on wrought-iron bars 10 ft. long, two of them retained their full elasticity under a strain of 11 tons per square inch, three bars bore 10 tons without injury, while one bore 9½ tons, and another, made from old furnace bars, did not retain its elasticity beyond a strain of 8¼ tons per square inch. All the links for the Pesth Suspension-bridge, upwards of 5,000 in number, and 12 ft. long from centre to centre, were tested without permanent set up to 9 tons per square inch, and those of Chelsea Suspension-bridge were tested without permanent elongation up to 13½ tons per square inch. Mr. Edwin Clark, from the results of his experiments, considers that the limit of elasticity of wrought iron is 12 tons per square inch, and this appears to have been adopted by him both for bars having a breaking weight of 24 tons and for plates having a breaking weight of 20 tons. Every chain cable purchased by the Admiralty is tested up to 11·46 tons per square inch of the metal in each side of the link, the standard test being 630 lb. for each circular ⅛ in. of the diameter of the iron of which the cable is made, one half of this strain coming upon each side of the link. The iron of which the cables are made does not, as a rule, take any permanent set when strained to this amount, or to say 11½ tons per square inch. Mr. Howard has stated that the best iron begins to stretch permanently under about 10 tons per square inch in 10 ft. lengths, although he occasionally tests up to 15 tons or 16 tons per square inch; the breaking weight being from 26 tons to 28 tons. Mr. Mallet, about four years ago, presented to the Institution of Civil Engineers the results of a valuable series of experiments on wrought iron and puddled steel, from which it appeared that the elastic limit and the breaking strain under tension were, in the case of certain samples, as follow:—

	Elastic limit. Tons.	Breaking weight. Tons.
Hammered slab or bar, 12in. by 4in.	15·312	24·062

Charcoal rolled bar from borings from the Horsfall gun	5·470	22·321

Sir Marc Isambard Brunel made a number of experiments on Yorkshire iron, hammered to small dimensions, or from ⅜ in. to ½ in. square. A very high elastic limit was obtained, as follows:—

Mean of ten bars, began to stretch with 22·2 tons per square inch, the mean breaking weight being 30·4 tons per square inch. With ten other bars the mean strain at which they began to stretch was 24·4 tons, the breaking strength being 32·3 tons per square inch. It is to be borne in mind, however, that these bars were reduced by the hammer only at the centre of their length and that, therefore, the stretching could be observed upon but a very small part of their length. Mr. John A. Roebling, the engineer of the Niagara Suspension-bridge, has made experiments upon bars similarly drawn down to ¾ in. square at the centre, the breaking weight being 33 tons per square inch; these bars bore a strain of 20½ tons per square inch without visibly stretching, and when no jar was given to the bars they would support this strain for a week. Upon any vibration, however, the bars immediately took a permanent set.

Under strains, however, considerably within the elastic limit, a gradual rearrangement of the particles of the iron commences; and if the strain be continued sufficiently long, permanent set will after a while take place. The late Monsieur Vicat, whose work on limes and mortar is so well known, began as early as 1830 to investigate the effect of continued strains on unannealed iron wire. He applied various strains to similar wires of a known breaking strength, and continued these strains from July, 1830, to October, 1833. One wire was strained to one-fourth its breaking weight, but beyond the elongation which at once took place no additional stretching occurred in thirty-three months. A second wire was strained to one-third of its breaking weight, and in thirty-three months it stretched at the rate of 2¾ parts in every 1,000 parts of its length, this stretching being additional to that which took place as soon as the weight was applied, but which, of itself, was not sufficient to immediately produce any permanent set. Under a strain of one half of the breaking weight, another wire stretched rather more than 4 parts in every 1,000 parts of its length. Under a strain of three-fourths of the breaking weight, a fourth wire stretched, in thirty-three months, 6½ parts in every 1,000 parts of its length, and then broke, which circumstance terminated the experiments. Monsieur Vicat's account of them appeared in the fifth volume of the second series of the "Annales de Chimie et Physique." It is to be regretted that, in place of the constantly recurring experiments upon the breaking strength of iron, and which, as is already beginning to be understood, give us but a very partial knowledge of its available working properties, we have not a larger experimental acquaintance with the continued supporting power of iron, as afforded by experiments similar to M. Vicat's. Mr. Fairbairn, it is true, made an extensive series of experiments between the years 1837 and 1842, to ascertain how long bars of cast iron would support weights equal to about 19-20ths of their breaking weight. By taking care to prevent any vibration in or about the bars, several of them continued, for five years and upwards, to support nearly their full breaking weight. Their deflection steadily increased, however, during the whole time, and Mr. Fairbairn has stated that some of these bars afterwards broke with but 1-20th of their original breaking weight. As bearing upon the last-mentioned circumstance, it may be remarked that M. Vicat, writing in in 1833, observed that Monsieur Henri, an engineer serving in Russia, had already shown that iron which had once withstood a great proof strain often broke some time afterwards under a much less strain. This fact must indeed have been known to practical men even earlier than in 1830.

Now, in employing iron in any structure where it is subjected to strain, we seek to keep within its limit of elasticity. Yet not only have we but a comparatively small number of recorded experiments to show us what this limit is, even under a single and temporary strain, but we have, at least, the result of M. Vicat's experiments to show us that we cannot depend upon anything like this limit under a long-continued strain. What experimental knowledge we have goes to show that the original elastic limit of iron is greater when hammered than when rolled, but we are unable to count with any degree of certainty upon the ultimate superiority of hammered iron, in this respect, after long-continued strain. As a rule, also,—the abundant evidence of which it is not, perhaps, necessary to introduce into the present paper—all harsh, hard, crystalline irons have a higher elastic limit, in proportion to their breaking strength, than soft, ductile, highly fibrous irons—like Swedish bar, for example;—that is to say, the harder irons will bear a greater strain before taking a permanent set, although, as we shall presently have occasion to inquire, it may not follow that they are really superior to other irons which are more readily stretched, and which, indeed, may have an even less breaking weight. What information we have goes to show that there is no settled relation between the elastic limit and the breaking weight of iron; the former is much more variable than the latter, and can hardly be expressed at all as an average result, ranging, as it does, from less than one-fourth to more than two-thirds of the breaking weight: or if the elastic limit be taken irrespective of the breaking weight, the instances already cited show that the former varies from 3¼ tons up to 24½ tons per square inch in different qualities of iron, although the range in ordinary bar iron and plate iron is not nearly as great. Now, no engineer, in apportioning the strains in a structure, would think of working up to, or near to, the breaking strength of iron. His object is to keep within the elastic power of the material, not merely as ascertained by a single strain of a few minutes' duration, but the continued elastic power of the iron as exerted through a very long series of years. We ought by this time to have hundreds of trustworthy experiments upon this point where there is now one. If the safe working strength of a metal is limited, as it would appear to be, by its measure of permanent perfect elasticity, we may say that we hardly know, even yet, what is the strength of the materials we are constantly dealing with, notwithstanding that not a year passes without some addition to our stock of knowledge of breaking weights.

While we are about considering the permanent injury which iron suffers when strained beyond its elastic limit, it is to be understood that iron may be strained for a short time almost up to the breaking point without in the least diminishing its strength under a breaking weight subsequently applied. Indeed, in gradually applying the breaking strain to any sample of iron, it is clear that it must have borne 10 tons before it is subjected to a strain of 15 tons, and that it must have borne 15 tons before it is strained to 20 tons, and so on. Not only is this the case, but after a bar of iron has been actually broken under a tensile strain, the two broken portions of the bar will almost always require a still higher strain to break them. The weakest spot in the bar will fail first, and although the breaking strain will at the same time permanently stretch the bar throughout its whole length, the iron on each side of the fracture will still have its original breaking strength. Professor Barlow's Treatise on the Strength of Materials contains the results of several experiments made at Woolwich Dockyard, as follow:—

A bolt of Solly's patent iron was nicked at one place, and then broken by a strain of 26·7 tons per square inch. One of the pieces was then tried and broke at 29¼ tons. In the next experiment a bar of the same iron was first broken with 23½ tons per square inch, then again with 26¼ tons, a third time with 26½ tons, and a fourth time with 25¾ tons.

Mr. Thomas Lloyd, engineer to the Admiralty, made a like series of experiments a few years ago, on ten bars of SC crown iron, 1⅝ in. in diameter, and 4½ ft. long. The mean breaking weight at the first breakage was 23·94 tons per square inch. At the second breakage, with pieces 3 ft. long, the mean strength was 25·86 tons per square inch. At the third breakage, with pieces 2 ft. long, 27·06 tons per square inch; and at the fourth breakage, with 15-inch lengths, 29·2 tons per square inch. Mr. Lloyd's experiments have been held to show that iron was actually strengthened by stretching it, or, in other words, that by destroying the cohesion at one point, the cohesion was everywhere else increased. A more obvious explanation is, that the bars first broke at the weakest part, then again at the next weakest part, and so on. A variation of from 23·94 tons to 29·2 tons in the strength of the same bar is undoubtedly large, the greater strength being 22 per cent. more than the lesser, a difference which appeared to exist in each of the ten bars tried. It is well known, however, that hardly any two bars of iron have exactly the same strength, and Mr. William Roberts, manager of Messrs. Brown, Lenox, and Co.'s extensive chain cable works at Millwall, has cut a 12 ft. bar of iron into 2 ft. lengths, and found, on testing, that there was a difference of strength of 20 per cent. between the strongest and the weakest of these pieces. In the experiments of the Railway Iron Commission upon the extension of cast iron, the strength of Lowmoor cast bars was 7·325 tons per square inch at the first, and 8·152 tons at the second breaking. Blaenavon iron broke with 6·551 tons per square inch at the first, and 6·738 tons at the second breakage. Gartsherrie iron broke with 7·567 tons per square inch at the first, and 8·475 tons at the second breakage. Other cast-iron bars of a certain mixture broke with 6·6125 tons per square inch at the first, and 6·777 tons at the second breakage, the latter being at an unsound place. Upon these results the commissioners remarked that "it would appear that iron, repeatedly broken, becomes more tenacious than it was originally. This erroneous conclusion may be obviated by considering that it would be very difficult, if not impracticable, to obtain cast-iron bars perfectly sound and 50 ft. long. Fracture may be supposed to take place the first time at the largest defect, and subsequently at those smaller, until, finally, none remain." It is not intended, however, in the present paper, to entirely deny that the breaking strength of iron may be actually increased by being stretched when cold; and this point may be left as an open question. That iron is so strengthened derives some probability from the known fact that its strength is greatly increased by being drawn cold into wire, and also by cold rolling. When heated moderately, or to less than a dull red, and then stretched, iron is strengthened throughout. This treatment is known as thermo-tension; and in an extensive course of experiments made about twenty years ago by Professor Walter R. Johnson, for the United States Government, a total gain of nearly 30 per cent. in strength and length, taken together, was estimated to have been obtained with a variety of irons. A bar of iron, having a strength of 60 tons, was heated to upwards of 500 deg., and then stretched by 6¼ per cent. of its length, when it acquired a strength of 72 tons. Captain Blakely has lately proposed the same treatment of iron, and his experiments, it is understood, corroborate those of Professor Johnson. All the links made for the four great pitch chains employed, with the steamship Great-Britain's engines, for getting up the speed of the screw, were stretched ¾in. while at a dull red heat.

But from what has been said, it is not to be supposed that iron is not injured by excessive strains, notwithstanding that the metal strained may, when tried immediately afterwards, still retain its full breaking strength. The injury will appear when a subsequent working strain is long continued; and even without waiting for this, it will be found that the strained iron has been deprived of a large part, if not the whole, of its natural elasticity. In a paper of great value, read nearly seven years ago before the Royal Irish Academy, and afterwards published in a quarto volume, entitled, "On the Physical Conditions involved in the Construction of Artillery," Mr. Robert Mallet has laid down a useful measure of the working and ultimate strength of iron. Poncelot had already employed coefficients which indirectly expressed, not merely the elastic limit and breaking strength of iron, but the range also through which the force acted in each case in reaching these limits. Mr. Mallet has adapted these coefficients to the English standard of mechanical work, to wit: "foot-pounds;" and he represents the structural value of different materials, or of various qualities of the same material—in one case by the product of the elastic load in pounds into half the range, in feet or parts of a foot, through which it acts; and in the other case by the breaking weight in pounds multiplied also by half the range, in feet or parts of a foot, through which its acts. Mr. Mallet employs Poncelet's coefficients, as follow:—

T_e = foot-pounds in reaching elastic limit of tension.
T_r = ,, ,, to produce rupture by tension.
T'_e = ,, ,, in reaching elastic limit in compression.
T'_r = ,, ,, to produce crushing.

One half the weight into the whole extension, or, what is the same thing, the whole weight into half the extension, is adopted because the force gradually applied to break a bar must increase from nothing to the breaking weight. Upon Dr. Hooke's law, *ut tensio sic vis*, the weight of a grain will in some minute degree deflect or extend the heaviest bar of iron, and the deflection or extension will increase progressively with the weight applied, up to rupture. Therefore, if a bar be stretched 1 ft. and then broken with a weight of 33,000 lb., the work done will be the mean of zero, and 33,000 lb. into 1 ft., or 16,500 foot-pounds. This, as has been said, is the work done in the case of a gradually applied strain. If, however, the weight be applied without impact, but at the same time instantaneously, upon the bar, it will, so long as the limit of elasticity is not exceeded, and supposing the bar to have no inertia, produce twice its former deflection, and, therefore, twice the ultimate strain. For the weight, in falling through the distance of the deflection due to the load at rest, will acquire momentum sufficient to carry it through an additional distance equal to that of the static deflection. This may be best demonstrated experimentally with the aid of a spring balance. If, upon the plan of a balance sufficiently strong to weigh up to 40 lb., a weight of 15 lb. be placed, and this be then lifted to zero on the scale and there released, it will descend, momentarily, to nearly 30 lb. on the scale, and if there were no opposing resistances and the spring had no inertia, it would descend to exactly 30 lb. In the actual application of strains in practice a weight is never thus applied, but a consideration of what would occur under such circumstances is sufficient to show how important it is that vibratory action be not overlooked in considering the strains on bridges. It is to be remembered that this action of suddenly applied loads is only manifested in the case of the application of weights; for if the strain be produced by the sudden admission of steam or any other practically imponderable body, no additional deflection will take place beyond that due to the pressure acting statically. If steam pressure acted in the same manner in this respect as a weight, the steam indicator would show nearly or quite double the pressure acting effectively within the cylinder of the engine.

It will not be attempted in the present paper to enter fully into the application of the coefficients adopted by Mr. Mallett, for there are objections against, as well as reasons in favour of, their application. It is evident that T_r may be the same in two cases—in one of which a high breaking weight is exerted through a very short distance, and in the other of which a low breaking weight produces stretching through a correspondingly greater distance. But this coefficient does possess a value in taking account of the combined cohesive force and extensibility of iron, instead of the breaking strength alone. As Mr. Mallet justly observes, glass has a high cohesive force, and is, nevertheless, useless under strain, owing to its brittleness, while caoutchouc has great extensibility or toughness with but slight cohesion. The products, therefore, expressed by the coefficients in question do not afford a complete notion of the practical value of a given material unless the factors whereby these products are obtained are also given. The elastic limit of iron, however low, is not to be exceeded in practical use, whatever its range of elasticity may be; nor does it appear prudent to work into the neighbourhood of a high elastic limit when the elastic range is known to be small. It is not to be understood that the coefficients in question are intended to apply otherwise than in comparison of bars of equal length, else it would result that the measure of T'_e in a bar 50 ft. long, was one hundred times greater than that of a bolt 6 in. long, and of the same material and sectional area. For the purposes of the engineer a long bolt is not only no stronger than a short one; but, as it can be no stronger than its weakest part, it will follow that the average strength of 100 bolts 6 in. long, is likely to be greater than that of a single bolt of the same diameter and 50 ft. long. Every engineer must be aware of the importance of toughness in combination with cohesive strength in iron, but we need much more extensive and accurate information as to the former; and a consideration of Mr. Mallet's coefficients should lead to additional experiments being undertaken. It is but right to mention here that, in 1848, Mr. Homersham Cox contributed a paper to the *Civil Engineers' and Architects' Journal*, in which he represented the mechanical work, in foot-pounds, expended in deflecting a girder, the work being expressed by the product of half the weight into the range of deflection. Mr. Kirkaldy, proceeding upon an independent course of inquiry, but with the same object as that pursued by Mr. Mallet, has lately published the results of a most important series of experiments, which are the first upon anything like an extensive scale, to take into account the combined cohesive force and extensibility of iron and steel. Mr. Kirkaldy experimented upon many hundreds of specimens, but he did not ascertain their limit of elasticity. He has given both the original dimensions and cross sectional area, and the dimensions and area after fracture; and he has also given the amount of elongation at fracture, although he did not ascertain the extension of the elastic limit. The reduction of diameter of a bar at the point of fracture serves to give a practical man a good idea of the quality of the iron, but it does not admit of an expression of the mechanical work done in producing fracture, as does the combined breaking weight and linear extension. In tearing a bar in two, also, we have to consider the permanent stretch communicated to all parts of the bar alike, and the additional stretch at and near the point of fracture. That part of the stretching which extends uniformly throughout the whole bar would, we may suppose, be exactly proportional to the length of the bar; while that part of the stretch which takes place close to the point of fracture would, we may also suppose, be a fixed quantity, whatever might be the length of the bar. Mr. Kirkaldy's specimens of iron and steel varied from 2·4 in. to 8·2 in. only in length, and with these the ultimate elongation at fracture varied from nearly nothing to 27 per cent. of the original length, whereas longer bars would have shown a proportionally less elongation. The samples which hardly elongated at all were of puddled steel ship plates. One sample, which bore 63,098 lb. per square inch of the original area, stretched before breaking but the 1-20th part of an inch in a length of 7·6 in., or less than 7-10ths of 1 per cent. of the length. Adopting Mr. Mallet's coefficient, the structural value of such a material would be almost nothing. In fact, Mr. Kirkaldy found the puddled steel plates, throughout, to have much less extensibility than cast-steel plates, while the former, also, were of very irregular breaking strength. The interest attached to the subject of puddled steel may possibly serve as a justification for mentioning this fact, although foreign to the object of the present paper, which has to deal with iron.

We have, up to this point, considered the elastic limit or permanent supporting power of iron under a single application of strain, extending in some cases over a few minutes, and in others over some months. We have very little experimental knowledge as to the extent to which we may approach the elastic limit under continued strains; but there is a probability that a continuous strain much exceeding one half of the elastic limit would be attended with gradually progressive permanant set. At the same time, with good iron, possessing a fair amount of extensibility, a single temporary strain, producing a slight or even considerable permanent set, may not diminish materially the strength expressed by Mr. Mallet's ce-efficient T_r, and the iron may still hold up indefinitely with an ordinary load considerably within the limit of elasticity. But, apart from the consideration of the time through which a strain acts, we have also that of the frequency with which the load is applied and removed. Mr. Fairbairn loaded cast-iron bars to upwards of nine-tenths of their breaking weight, and this load remained on for from five to seven years before the bars broke down; but with a repeated application and removal of load, the Iron Commission experiments showed that iron bars, when repeatedly deflected by impact through one half the distance due to their breaking weight, broke down after from 130 to 4,000 applications of the strain. Mr. Fairbairn communicated some of the results of an important series of experiments to the British Association at the Manchester meeting, 1861, from which it appeared that a large model of a wrought-iron plate girder withstood, without injury, 1,000,000 applications of a load equal to one-fourth its breaking weight, and afterwards 5,175 applications of one-half its breaking weight, when it broke down. The model was then repaired, and 25,900 applications of two-fifths its breaking weight, and afterwards nearly 3,000,000 applications of one-third its breaking weight, were made, it was said, without injury, although neither the deflections nor the permanent set were given. We know that iron alters its form, temporarily, during the application of very moderate strains, the elasticity of good iron being generally observable with strains of one ton per square inch. And we know that its form is permanently changed, both immediately on exceeding the limit of elasticity, and gradually under strains nearly approaching that limit. There clearly must be a rearrangement of the particles of iron always going on where the strain is great; and as we know that when even a more moderate strain is eased off the iron tends to resume its original form, it appears incontestible that final injury must result under what may appear moderate, although irregular loads—say one-third, or even rather less of the breaking weight. Iron, it is still to be remembered, has not been employed long enough for purposes of construction to enable us to compare its endurance with masonry, of which there are abundant examples still perfect after many hundred years. At the same time, it must not be forgotten, that, while we can never know the absolute strength of a bar of iron without destroying it under strain, neither can we always infer its strength from its deflection, or apparent range of elasticity; for we are not yet secure against flaws or those other faults of molecular structure which Mr. Mallet so well describes as "planes of weakness." A bar of iron may have a general strength of 22 tons per square inch, except at a single point in its length, where, for an almost inappreciable linear distance, the strength may not exceed 10 tons. If the bar be broken this fault will be detected, but hardly, if at all, otherwise; for under a strain of even 8 tons or 9 tons, the extension at the precise point of weakness would be so slight as to be quite overlooked in a general observation of the total deflection or extension.

In this fact, which was mentioned thirty years ago by M. Vicat, and in the known effects of suddenly applied strains, vibration, impact, &c., we have abundant reason for extreme caution in the use of iron for permanent structures of any kind. It can hardly be said that the Board of Trade limit of 5 tons, arbitrary as it is, is too moderate, although there should be some account taken of the known quality of the iron to which this strain is to be applied; and it may not be necessary to adopt an unlikely load as that which is to produce the maximum strain of 5 tons. The recent discussion as to the security of Chelsea Bridge affords much suggestive material upon these points.

The application of iron to bridges, especially to those of large span, necessarily requires the most careful consideration in apportioning the strains, since every pound of metal not brought into effective action, is so much dead weight or useless load—being not only misapplied of itself, but requiring additional material to support it. In considering the strains upon iron, therefore, reference has been more particularly made in the present paper to its employment in bridges; but in the case of boilers, iron ships, cranes, ordnance, railway bars, warehouse girders and columns, roofs, engine beams, and in many other applications, the most careful distribution of material and adjustment of strains is of very great importance. Iron is, perhaps, more severely strained in steam boilers than in other structures. In the case of locomotive engines, there is a disposition to employ still larger boilers and to carry still greater pressures. With 50 in. boilers, formed of 7-16 in. plates, double rivetted, and carrying, as is now not usual, from 130 lb. to 140 lb. pressure, there is at the higher limit a circumferential strain of 5¼ tons per square inch at the joints, and a longitudinal strain of nearly two tons per square inch along the whole length of the boiler, the resulting strain at the joints being nearly six tons per square inch. This strain is constantly maintained with plates ranging from 21 tons to 24 tons in strength, and under all the contingencies of corrosion, incessant vibration, and occasional sudden exaltations of pressure due to the instantaneous production of steam upon overheated tubes or plates. In many cases we have 4 ft. boilers with ⅜ in. plates, single rivetted, and worked at 120 lb., corresponding to a strain of at least 6¼ tons per square inch at the joints of the boiler when new, the circumferential and longitudinal strains being both taken here into account. Put under this strain when new, many locomotive boilers are worked in all from ten to twenty years, and often from three to seven years, without any internal examination of the plates. It is not remarkable, therefore, that explosions are becoming so frequent.

We may regard with much hope the increasing use of steel in large masses, as prduced by Krupp and by Mr. Bessemer, and others whose discoveries have already effected a great economy in the production of that material. Although a departure from the subject of the present paper, it is interesting also to refer to the introduction of phosphorised copper, as now produced by the Birmingham and other coppermasters. It was announced, about three years ago, as a new discovery by Mr. Abel, chemist to the War Department, that the addition of from 2 to 4 per cent. of phosphorus to copper greatly increased its density and strength. There is no doubt of the large advantage of this combination, although it was discovered in the last century and made publicly known sixty years ago. A French chemist, M. Sage, contributed a paper upon this subject to the *Journal de Physique*, and which was translated into the 20th volume of the *Philosophical Magazine*, for 1805. By combining the maximum quantity of phosphorus with copper, the latter acquired the hardness, grain, and colour of steel; and although M. Sage had already kept the compound for fifteen years, it had suffered no change from exposure to the air. It was easily turned and took a fine polish. It may yet be found that copper thus treated is the best material for many of the purposes of the mechanical engineer.

In conclusion, it must be regretted, if not indeed, deplored that our exact knowledge of the permanent supporting power of iron is so limited. The present paper, it is feared, will hardly fulfil its title, which may have led to the expectation that some definite relation would be assigned between the safe load and the ultimate strength of iron. Even at the risk, however, of leaving the subject as the author found it, he indulges the hope that the considerations which have been touched upon may induce closer observation and inquiry into the real working properties of iron, as distinguished from its ultimate strength. The question involved in this subject does not appear to be one which admits of solution by a reference to any known natural law, nor does it appear that it can be disposed of by mathematical investigation, but our only safe conclusions must be derived from the results of protracted, varied, and repeated experiment. In the meantime common prudence requires that we ascertain, with as much accuracy as possible, the elastic powers of every given kind of iron proposed for permanent works, and that we then so proportion the parts that the working strain shall never much exceed one half the elastic limit—a ratio which will correspond, according the variable quality of iron, with a load of from 1-8th to 1-4th its breaking strength.

SAGAR AND ROCLIFF'S IMPROVEMENTS IN MOULDING.

A PATENT has been obtained by Messrs. Sagar and Rocliff, of Burnley, Lancaster, for improvements in the mode of constructing the parting plates for producing the moulds requisite in casting iron, brass, and other metals. The invention will be well understood by referring to the engravings. *a* is the parting plate, which is suitable for moulding toothed wheels having five arms or spokes; the parting plate is made of metal or other material. In Fig. 1, the recesses marked *b*, *b*, correspond to the spokes of the pattern to be moulded; the boss and the inner diameter of the rim of the wheel are also produced in recess in Fig. 1. The projections *c*, *c*, are for the gits or runners. When using the parting plates described for moulding wheels, the plate *a* is placed between the boxes *e* and *f*, with the wheel pattern *d* upon it, the position of the wheel pattern being determined by the recesses in the face of the plate, and the two are held in position by pins passing through the snugs of the moulding box, and through the holes in the plate *a*; the sand is then rammed in round the pattern in the usual manner; after this is completed the moulding boxes *e* and *f* are turned over, the whole being held together by the pins; the sand is then rammed into the upper half *f* of the moulding box, and the git hole *g* prepared in the usual manner. The two parts of the moulding box are now ready to be separated, and when the top box is lifted off the plate *a* is removed; the moulder then lifts the wheel pattern out of the sand, after which the two halves of the moulding box are put together, thus completing the mould, into which the molten lead is run in the usual manner. It may in some cases be preferable to fix or attach the pattern to the parting plate instead of using them separately. When the patterns are fixed to one side of the parting plate, they are of course lifted out of the sand with the plate, and as the back of the plate is of the shape of the inside of the pattern required the boxes when put together form the mould.

FIG. 1.

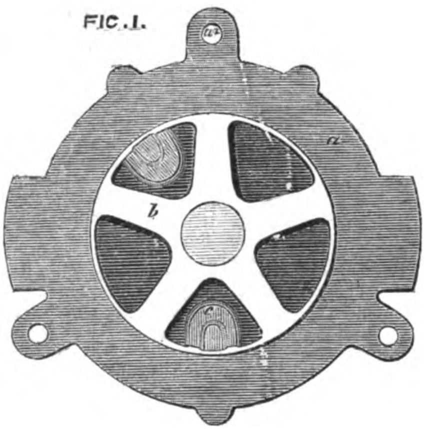

FIG. 2.

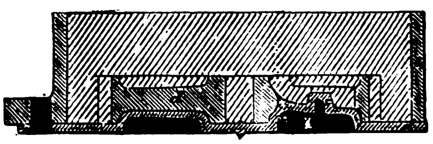

FIG. 3.

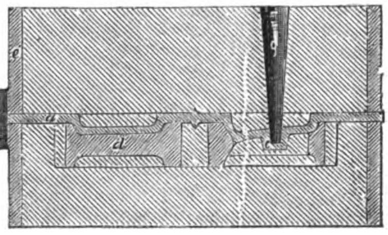

CLARKE'S PATENT ADJUSTABLE SCYTHE.

THIS invention, recently patented by Mr. J. G. Clarke, of Brackley, Northampton, consists in forming the crew or heel of a scythe blade with a recess, and in such manner that it may be fixed by a wedge in a hollow socket, which is fixed or formed, by preference, on the end of a tube, which is passed into and fixed in a hole formed up the lower end of the sneath or handle of a scythe in place of forming the crew or heel of a scythe blade with its end turned up at an angle in order to its being fixed as heretofore to a wood sneath or handle.

Fig. 1 of the engravings shows an elevation of part of the crew or heel of a scythe blade and of a hollow socket in which it is fixed by a wedge; fig. 2 is a section of the same. *a* is part of the crew or heel of a scythe blade, in which a recess, a^1, a^1, is formed which corresponds with the length of the hollow socket *b*, which is for the purpose of obtaining strength and lightness fixed or formed on the end of a tube *c*, which is to be fixed to the lower end of a scythe handle; *d* is a wedge which retains the crew or heel within the the socket. It will be seen that the heel or crew of the scythe blade, in place of being turned up at an angle in order to its being fixed in the ordinary manner to a sneath or scythe handle, is only slightly curved near its end, whilst the end is formed with a recess to fit the socket, by which the end of the crew or heel, in place of rising up the lower end of the scythe handle, as heretofore, is formed so as to be held at right angles to the end of the scythe handle.

FIG. 1.

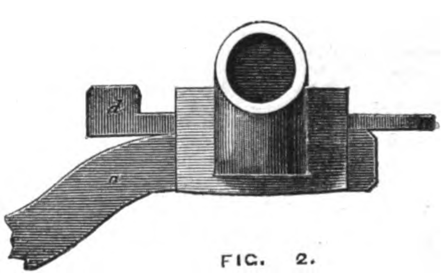

FIG. 2.

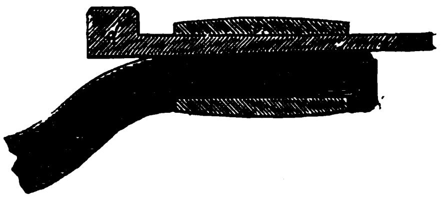

FIG. 3.

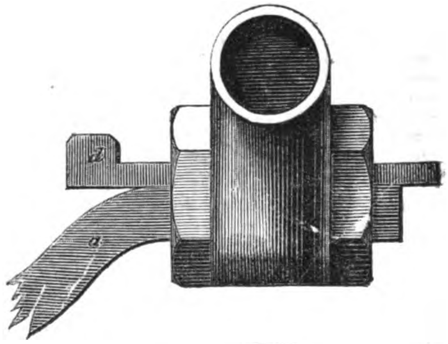

FIG. 4.

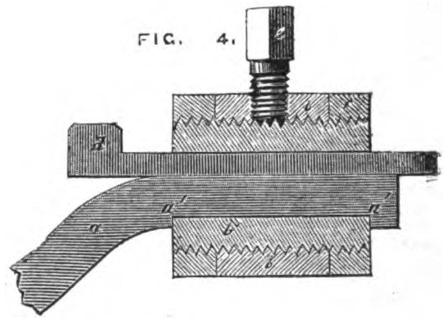

Fig. 3 shows an elevation; fig. 4, a section, wherein *a* is the heel or crew having a recess, as in the previous figs.; *d* is the wedge by which it is fixed within the socket *b*, which in this arrangement is formed of two parts *b*, *b*, which, as before described, is by preference fixed by a short tube to the handle of a scythe.

The internal part is retained by a set screw *e*, and two screw nuts *f*, *f*, as shown, by which the position in which a scythe blade is held may be more nicely adjusted, or the two nuts may be dispensed with, and the set screw only used. In some cases, in place of an ordinary handle, the tube *c* is extended so as to form a tubular metal handle.

LAHOUSSE'S IMPROVED RAILWAY WHEEL.

This invention, just patented by Mr. Lahousse, of Lupus-street, Pimlico, relates to a novel construction of a railway wheel, which will admit of the application of tyres in a cold state, and of their ready removal when required to be renewed.

In the accompanying engravings, Fig. 1 shows the improved wheel in side elevation; Fig. 2 a cross section; and Fig. 3 shews the boss of the wheel in face view, with one of a series of segments, used in lieu of spokes attached thereto.

A is a wrought iron nave, formed with a conical periphery, and having a broad flange at the base of the cone, which flange is to be pierced with bolt holes. In lieu of spokes discs are employed, which are divided radially into segments, as shown. The outer ends, 1 1, of these segments are bent over inwards, so that when the segments are brought together the bent-in or perimetal edges of the discs will butt against each other. If thought desirable, the adjacent edges of the segments may be coupled together by means of a strap piece and rivets. The segments of the two discs are arranged in pairs, and their inner ends are kept apart by means of filling pieces F, which are pierced with bolt holes. Through these filling pieces, and also through the segment, bolts *f* are passed for securing the pairs of segments together. The segments are arranged around the boss A, within the cold tyre C, which is formed on its inner periphery, with a dish-shaped face or annular trough to receive the turned-over ends of the segment pieces. Wedge pieces E are inserted between each pair of segments. These wedges are driven inwards, until the pairs of segments have moved sufficiently radial (by the pressure thus applied to them) to bed themselves firmly in the annular recess formed in the inner periphery of the tyre. When the wedges are driven home and the consistence of the wheel is secured, the nave is bored out, and the projecting end of the wedges E are turned down; an annular plate or cap D covers the outer ends of the wedges, and prevents them working loose; this plate is secured by screw bolts, which pass through the flange of the nave A, through the segments and filling pieces, and through the plate or cap D, and receive on their tapped ends the nut *e e*. When the tyre is worn or otherwise injured, by merely removing the cap D and knocking out the wedges, it may be disconnected from the wheel, and may be readily replaced by a new one.

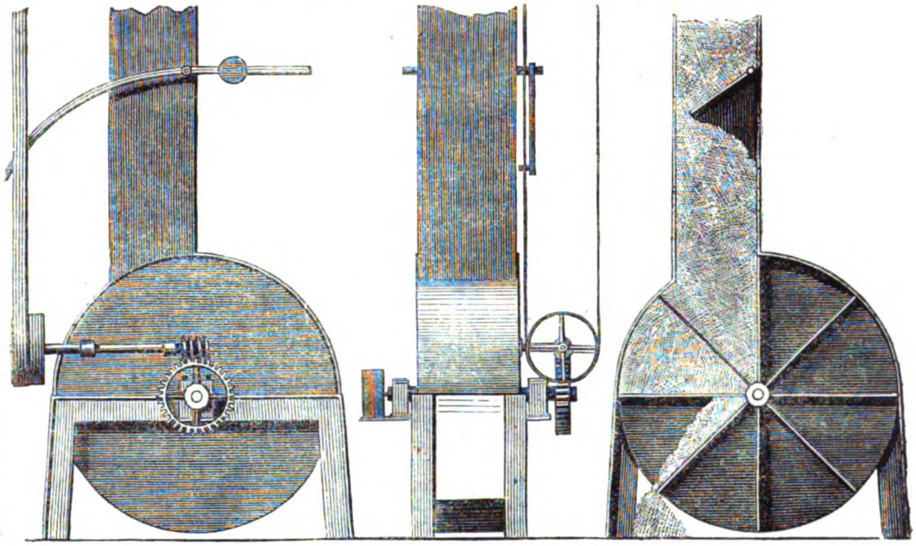
KING'S APPARATUS FOR MEASURING GRAIN.

Mr. T. King, of Spitalfields, has obtained a patent for an apparatus for measuring grain. For these purposes a measurer is employed having two circular ends, the space between the two ends being divided radially by partitions, so as to produce angular measuring chambers around the central horizontal axis, on which the measurer is caused to turn (as illustrated in the annexed engravings.) The axis of the measurer turns in bearings carried by the framing of the machine, the upper portion above the axis being covered in by a bent plate, or cover, in the form of a semicircular arch, which is fixed to the framing. There is an opening through the cover where the lower end of a hollow trunk, or pipe, is attached, which trunk, or pipe, descends from an upper floor, or place from which the grain or other substance descends through the trunk pipe to the measurer. In the hollow trunk or pipe is a valve the axis of which has a weighted lever fixed on it, and such lever is arranged to act on the driving strap (which communicates rotary motion to the axis of the measurer) and causes such driving strap to be moved from the driving pulley on to the loose pulley, when the weight of the lever overcomes the valve, by reason of the supply of malt, grain, or granular substance being insufficient, and the machine will thus be stopped, but so soon as the weight on the valve caused by an increased supply of the substance to be measured is sufficient to overcome the weighted lever, the driving strap will be again moved from the loose pulley to the fast one, and the machine be again put in motion. The driving pulley is on an axis on which there is a worm or screw, which gears with and drives a worm or screw wheel on the axis of the measurer. The malt, grain, or other granular substance is delivered from the measuring compartments as the radial partitions descend below the axis of the measurer. The measuring chambers or compartments are each capable of measuring a bushel or other determined quantity of material.

This apparatus does not require to be attended whilst it goes on measuring. A counting apparatus is applied to the axis, by which the quantity of malt or grain or other granular substance which has been passed through and measured by the machine may be ascertained at all times.

KING'S APPARATUS FOR MEASURING GRAIN.



INSTITUTION OF CIVIL ENGINEERS.

January 20 and 27, 1863.

John Hawkshaw, Esq., President, in the Chair.

The discussion upon Mr. Preece's Paper "On Railway Telegraphs, and the Application of Electricity to the Signalling and Working of Trains," occupied both evenings.

It was observed that two statements had been made in the "Private Press" abstract, which required explanation. The first referred to the system introduced upon the London and North-Western line by Mr. Edwin Clark. In alluding to the use of disconnecting wires it was remarked, that "this plan was thought to be dangerous." By this it was not meant to be implied, that danger was induced to the traffic of the line, but that the wires were liable to cause derangement in the electrical circuit. The second had reference to the instrument recently applied to the Metropolitan Railway by Mr. Spagnoletti, which, though identical in principle with one invented by Mr. Highton in the year 1854, was admitted to differ considerably in detail.

It was thought the necessity for an opportunity of discussing this subject would be apparent, when it was understood that no two lines having their termini in London employed the same system, and that on some lines more than one method was in use. The reports of the inspecting officers of the Board of Trade upon Railway Accidents were also at variance with each other, in this respect. Perhaps the most important point for consideration was, whether lines should be worked by an interval of space, or by an interval of time. The Government Inspectors recommended the former plan, while the managers of the principal railways contended that the traffic could not be carried on under such restrictions, and that reliance must be placed on the latter system.

It was explained that in Dr. Tyer's system, the dial of each instrument was divided into two parts, the upper portion referring to the "up" line, and the lower portion to the "down" line. Each instrument had also two indicators—one red, the other black. The former always showed the last signal sent; the latter that last received, and this was unalterable by the man in charge. No signalman ever sounded his own bell, or gong; and when these were heard, the man knew that the next station wished to communicate with him. As regarded the effects of atmospheric electricity, it was asserted that it had never caused a false signal to be given; and as the red needles were altogether out of circuit, and could not therefore be affected by lightning, the chance of demagnetization from this source was reduced one-half. Further, the needles were not permanent magnets, as in most other instruments, but simple pieces of soft iron, which received their magnetism by induction, from being suspended in close proximity to the coil of wire through which the charge flowed. As to the objection that this system only required one line wire, it was believed to be an element of safety, as well as of economy; for where two or more wires were employed, if one were broken, with persistent currents flowing through the fractured wire, or either of the others, false signals might pass into the instruments; whereas with one wire, should it be broken, no signal could be acknowledged, and thus be made complete. As to the instruments being always under lock and key, it was argued that when any derangement occurred, it was safer to send for the superintendent at once, than to allow the signalmen to attempt to repair, alter, or tamper with what they knew nothing about; and it was considered, that all "terminals" and connections should be under lock and key, as a signalman might put the wires on to the wrong "terminals" which, with persistent currents and needle arrangements, would cause a different signal to be recorded at the distant station to that transmitted.

As the extensive system of telegraph train-signalling on the South-Eastern Railway—the basis of which was "sound upon bells"—had only been cursorily alluded to in the Paper, it was considered advisable to give some further details. The first bells were erected January 22—31, 1852, and at the present time 275 miles of that line were protected in every possible manner, and in a great variety of places, by bells—there being 330 in operation, some connected merely in pairs, others with intermediate bells, and in different ways. Of these, 84 were provided with counting indexes, which showed the number of blows sounded, and the remainder were plain. In some of the signal-boxes there were two, three, and, in rare cases, as many as four bells, which differed in tone, and in the position they occupied. Should the signalman be uncertain which bell sounded, or how many blows had been struck, the index pointed to the number on a dial. It was a simple mechanism—a pair of pallets and a scape-wheel on the arbor, which carried the hand of the index to the precise number of blows struck upon the bell. The total cost on the whole line, had amounted to nearly £3,650, being at the rate of £13 5s. 3d. per mile, including wires, bells, and batteries complete. The hammer, which was attached to the keeper of the electro-magnet, was the only moveable part of the bell apparatus. The signals were given by the number of blows struck, and one fundamental and essential condition was, that every signal should be correctly repeated before it was allowed to be complete. In every system of train-signalling, it was essential that a good understanding should be established between the men at two neighbouring stations, A and B. On the South-Eastern line, the four telegrams which were necessary between them were—1st, "May I send a train," given by station A, striking one blow to B; 2nd, "Yes, you may," one blow struck back by B. Nothing could be simpler. The blow was a loud one, distinct in its sound, and readily understood. The third communication would be from B, 3rd, "The train you sent is in safe," intimated to A by three blows; to which the fourth message sent back from A, 4th, "All right, I understand train is in," A repeating B's three blows. These four signals were booked by each station; the time at which each signal was completed being entered in the proper column, so that a double permanent record was secured. On the three lines on the west side of the London viaduct, run over by the South-Eastern, the Brighton, and the Croydon and Crystal Palace trains, where the bells alone were used, the average number of trains on week-days was 196, and in one year 78,676; and on the day of the Forester's fête at the Crystal Palace, August 19, 1862, 535 trains were booked, as having been *bona fide* signalled by one pair of bells. It was satisfactory to be able to add, in proof of the efficiency of this system of train-signalling, that no collision had ever occurred on the portions of the South-Eastern line where the bells were in use.

One peculiarity about these instruments was, that they appeared to be the only kind of telegraph that could be used with balanced currents. When the bells were arranged in this way, the guard of a train which might have become disabled between two stations, had merely to fasten a wire to the bell-line wire, and each time he touched a rail with the other end of the wire, the bells at the adjacent stations on both sides were rung. No batteries or apparatus of any kind had to be carried with the train. The system of signalling was, however, so efficient on the South-Eastern line, that such a use of the bells was hardly to be looked for.

It was believed that the South-Eastern Railway Company carried out the "block" system of telegraph train-signalling to a greater extent than any other in the United Kingdom; and that, as it was the only system which could be followed with any degree of safety, especially where the trains were run at high speeds and at irregular intervals, to suit the emergency of the traffic, it ought to be made obligatory upon every railway company. On the other hand, it was argued that, upon a main line of railway, the use of the "block" system would be disadvantageous, as being liable to lead to greater detensions than were called for upon any ground of public safety, and as having a tendency to lessen the caution necessary to be observed by engine-drivers. Although there might be portions of a railway so crowded with traffic, that the telegraph would become an essential element of safety, and where this system might answer very well, yet so long as its aid could be dispensed with, there was a positive advantage in ignoring it, and in depending upon the ordinary mode of signalling; for the "block" system required such a greater number of signals and signalmen, as to increase the liability to mistake, and so render the alleged additional safety very questionable.

It was remarked, that both the ear and the eye were apt to be misled—the ear especially; and that as the continual and monotonous repetition of the same sound must have the effect of confusing the mind, the bell-system could not be trusted. The eye, too, was liable to error, and the constant motion of the needles to produce weariness. It has been ascertained, that the best clerk in the Electric Telegraph Company's service made a mistake once in five thousand five hundred and eighty times. Although in the simple work of signalling trains "in" and "out" the mistakes would be fewer in proportion, yet it was generally admitted, that the Electric Telegraph was a dangerous instrument to trust, as the primary agent in the working of a railway. As an auxiliary, however, telegraph train-signalling was believed to be invaluable, and its application indispensable; for it enabled managers to expedite under extraordinary circumstances, the passage of trains, to economise time and money, and as a corrective of other signals it was productive of increased safety.

The several instruments by means of which the "block" system could be carried out were then described. In reference to Mr. Tyer's instrument it was remarked, that although perhaps one wrong signal might be sent by a current of atmospheric electricity, yet no series of false signals could be transmitted, as might happen if the magnetism of a needle were reversed. In this system batteries were not permanently closed, and the current was not kept constantly flowing through the wires; consequently the batteries did not deteriorate so rapidly as in those systems in which a permanent current was maintained. But this instrument had what might be considered a serious fault, for, to send one and the same signal, two different buttons had to be used at two different times, according to the position of the red pointer; and if the wrong button was chosen, the needles showing the condition of the line would be altered when they ought not to be moved. In Mr. Preece's instrument there were several hinges, and at each there was a liability to stick. In addition there was a cog-wheel and rack, and the great motion of the semaphore arm, as compared with the small motion of the armature, placed the latter at such a disadvantageous leverage, that the slightest check to the end of the semaphore arm would prevent the motion of the armature, whether moved by the current, or by the weight, unless very powerful currents were had recourse to; and the utmost force caused by the electric current was very feeble. Moreover, the working parts were exposed to dust and dirt. It was thought that Mr. Walker's bell-system, and other instruments which did not leave a permanent visible signal, threw too great a strain on the attention of the signalman. Mr. Edwin Clark's system, as in operation on the North Western Railway, was believed to have fewer practical objections, and therefore to be safer, than any other. The instrument he employed was made of a common magnetized needle, balanced on two pivots. There was the least possible amount of friction to restrain the motion of the needle, the action was of the simplest kind, and the instrument was scarcely liable to be deranged.

It was urged that no system of mechanism intended for train-signalling should be capable of being used for any other purpose. Also, that if the distances between the signal stations were made to correspond with the maximum amount of traffic likely to arise on any particular section of a line, the objection to the block system, that it unnecessarily delayed the traffic, would be at once removed. It was singular that, whilst it was attempted to ignore the advantage of the block system on the open line, its importance was admitted in tunnels, where the greatest caution was required. One great defect in all the systems previously noticed was that arising from the failing of the batteries. In Professor Wheatstone's arrangement of magnetic signals, as there was no voltaic battery, there could be no diminution of power; so that the instruments would be as available twenty years hence as at the present time. They also possessed a great surplus of power beyond what was required for train signalling; and could be, and had been, arranged to give a large number of signals, in addition to the two simple ones of "train on line," or "line clear."

The ordinary station signals now in use gave three signals—"all clear," "danger," and "caution." As they were almost invariably maintained either at "danger" or at "caution," the latter signal was frequently taken to mean "all clear," and being thus disregarded, not only had it no value, but an element of danger was introduced. On the Great Western line, the "caution" signal was given by a policeman with his hand on peculiar occasions only, and when really required.

It had been ascertained by experience, that the signalmen preferred the system of permanent signals to those in which the same wires were used for both lines of rails, and by which trains were simply "reported" as in or out of a tunnel. As an illustration it was mentioned that, at Springwood, near Huddersfield, where there were three cabins with telegraphs, so much impressed were the men with the necessity of having a permanent signal, that they invented one of their own, consisting of a piece of red rag placed on the instrument when there was a train in the tunnel, and removed when it was reported clear. This red rag had now been replaced by a card. Bells to indicate "line clear" or "line blocked" seemed more objectionable than the system of temporary needle signals, as the eye was more to be depended upon than the ear. The repetition of signals was the best safeguard against error, and against failure from demagnetization, reversal and accident to the wire, or to the apparatus from any cause.

It was remarked that the Metropolitan Railway was worked entirely by telegraph; the trains being controlled by station semaphores, moved by the signalmen. During the first three weeks it had been opened, more than half a million passengers had been conveyed over the line, and on one occasion the number amounted to nearly forty thousand within fifteen hours, and no mistake had occurred in the working. The instruments employed were the invention of Mr. Spagnoletti. In their normal condition, when not in action, or in case of derangement, neither signal was distinctly visible. This line was blocked by pressing a red key, when the disc at both stations showed the red colour, and the words "train on line." The colour indicated by the disc was always identical with that of the key upon which the finger was placed. The white disc signal was given for "line clear." Either could be seen from any part of the signal-box with a moderate light, and it was considered that the marked distinction offered by the broad discs of different colours (red and white) constituted of itself an advantage over the needle signal.

With regard to the working of single lines of railway, it was contended that the only system which would ensure absolute safety was the "train staff." In the manipulation of the telegraph, one mistake might be fatal, whereas the "train staff" could scarcely go wrong, as to produce a collision there must be the consentaneous mistake of three men—the station master who had charge of the staff, the guard, who received it from the station master, and the engine driver, who could not move till the staff was produced. To this it was replied, that the "train-staff" system had been found by experience, in Ireland, to be exceedingly defective, as even when running only five trains per day in each direction, it was almost impossible to repair defects on the line without working in the night, or to run extra trains at times of fairs and markets. On the other hand, it was asserted that the "train staff" had answered well in a great number of cases, both in England and Ireland, and that not a single accident had occurred, from trains meeting one another, where it was employed; whilst where telegraph instruments had been used without a "train staff," there had been a number of accidents under various systems of working, in consequence of mistakes and misunderstanding on the part of the persons in charge of the instruments. In answer to this it was observed, that the alleged inefficiency of the telegraph in the working of single lines was due, as far as could be ascertained, more to the eccentricity of genius on the part of the railway officials, than to the system itself when worked under proper guidance; inasmuch as in India about 2,000 miles of single lines (or considerably more than all the railways in Ireland put together), were worked by the telegraph with comparative freedom from accident. Thus, during the year 1860, out of 4,225,240 passengers carried in India, none had been killed from causes beyond their own control, while only 0.94 per million had been injured. According to the English returns for the past year, the passengers carried were 173,721,139, the number killed averaged 0.26 per million, and those injured 4.50 per million. Again, one-half of the accidents on English lines arose from collisions, while on the Indian railways one-seventh only emanated from the same cause. Theoretically, no doubt, the "train-staff" led to greater safety than any other mode of working. But persons might be preserved from railway accidents by not going upon a railway at all; and the "train-staff" system was an approach to doing away with railway travelling. As a system it simply meant that, provided a company confined itself to one staff, it would also limit itself to one locomotive; and so long as only one locomotive ran upon a line there could not be any collision. But it was obvious that, under that system, trains could not be started from the same end of the line at short intervals of time, and therefore it was considered wholly inapplicable to any railway on which the traffic was large.

It was stated that, in the year 1854, Mr. C. V. Walker constructed a semaphore electric telegraph for train signals, which exactly coincided with that described by the author. It consisted of a galvanometer needle, with an ivory arm on the top of a semaphore pole instead of an outer needle, a persistent current causing the arm to be retained in one of its positions. This instrument was used at Tunbridge for eight months, and was shown at the International Exhibition at Paris, in 1855. At the same time Mr. Tyer exhibited a pair of disc signals, coinciding in many points with the French plan of using discs. Experiments were tried on the latter system on the Paris and Strasburg line, and at present there were about 150 sets of these instruments at work on the Continent.

In reply, upon the discussion, it was observed, that the first great question was the advantage of the general adoption of the telegraph in the working of railways. Those who had spoken seemed to confirm the opinion expressed in the Paper, that the telegraph was chiefly valuable as an auxiliary agent. Railway companies did not appear at present to have arrived at any definite conclusions, as to the point of demarcation where it was necessary to abandon the "time" system, and to seek the aid of electrical signals. It having thus been determined that, in certain localities, and under certain circumstances, a system of electrical signalling was essential, the question arose, whether the telegraph was to be dependent upon the organs of sound, or upon those of sight. Although the South-Eastern, the London, Chatham, and Dover, and the North-Eastern Railway Companies employed bells, it was contended that the weight of the evidence was in favour of visual, as against aural signals. The next point for consideration was, whether these visible signals should be produced either in a permanent, or in a transitory manner. As the use of transitory signals necessitated the employment of record books, it was believed that they were disadvantageous, as record books could never be trusted. In discussing the question whether these permanent signals should be obtained by the use of continuous, or by momentary currents of electricity various natural and artificial phenomena were referred to, which disturbed the correct working of telegraphic circuits. The first and greatest enemy was atmospheric electricity, and its most frequent effect was one resulting from the inductive action of a cloud charged with electricity. Such effects were stated to be comparatively harmless on the semaphore, to be easily remedied upon the needles; but to be highly dangerous, as giving false signals, on Mr. Tyer's and other instruments worked by momentary currents. Deflection, or "earth's currents" also seriously affected circuits worked by momentary currents. There were also interruptions arising from accidental and artificial causes, such as the wires coming into contact; these would produce false signals on instruments worked by momentary currents, while those actuated by continuous currents would remain unaffected.

With regard to the invention of the Semaphore Electric Telegraph, it was remarked that both Mr. Walker and Mr. Preece had been anticipated by Mr. Ward, in 1847. And although the idea conveyed in the two instruments in question was similar, their mechanical construction was different; for Mr. Walker's was a simple needle, whilst Mr. Preece's was a practicalr railway signal. The author did not, however, claim the mere invention of the semaphore; but the assimilation of the electrical to the ordinary line signals of the particular railway upon which they might be fixed, the method by which electrical signals were simply worked as distant signals, and the reduction of the whole system to one uniform plan.

ON OBTAINING FRESH WATER BY EVAPORATION.*

By Mr. George Russell.

When water is distilled by the usual method of merely condensing the steam, it is well known that, from the absence of its natural quantity of air, the taste is so obnoxious as to render it disagreeable, if not unfit for use, immediately on leaving the apparatus, or even after it has been for a considerable time exposed to the atmosphere. Even if the process of exposing it to the atmosphere were sufficiently effective, it would be most inconvenient on board ship, where a supply of fresh water is one of the most important requisites. From the intense action of distilled water on metals, considerable care is necessary to prevent it becoming impregnated with poison from the metallic surfaces with which it may come in contact. To obviate these defects by supplying the water with air during the process of distillation, the writer has applied the principle of induction by means of a steam jet—in a manner somewhat analogous to the blast pipe of a locomotive engine.

Fig. 1 of the engravings annexed is a section of this contrivance, and Fig. 2 a section of an ordinary worm distilling apparatus, with this "distil-aërator" (as it has been named) attached. The steam enters at S, its admission being regulated by the stop-cock. In the cup below the cock there is a diaphragm at right angles to its axis, and the steam nozzle reaches nearly down to this diaphragm, which is formed with a larger nozzle or tube concentric with the steam nozzle, and projecting downwards to about half the depth of the cup. Above the diaphragm there are apertures, A (Fig. 1), for the admission of air, with a cover, or valve, for shutting when the apparatus is not in use, or for regulating the admission. When steam is admitted at S, and, as it leaves the steam nozzle and passes into and through the lower nozzle, a current of air is inducted through the apertures at A. This mixture of steam and air passes through the worm, and combines in the process of condensation, any superfluous air being discharged along with the fresh water at W (Fig. 2). As already stated, the immediate design of this contrivance is to aërate the water, and thus bring it to the natural condition of fresh water; but, from experiments, it is found that, besides this, the efficiency of this apparatus as a condenser is greatly increased from two causes: first, the rush of air in contact with the steam assists, to a considerable degree, in its condensation; and, secondly, the total surface is rendered available for condensation. In explanation of this, suppose, as in the ordinary distiller, no air apertures to exist at A, the steam being condensed in the worm produces a partial vacuum, and the fresh water collects in the lower part of the worm, until a column sufficient to balance the partial vacuum is produced. The lower portion of the worm is thus inefficient as condensing surface in ordinary distillers; but when air is admitted at A, the vacuum is destroyed, and all the surface is rendered efficient.

The experiments have shown this method of aërating the water to be most efficient, the water being discharged cool, sparkling, and as agreeable to the taste as spring water.

---

* Proceedings of the Institute of Engineers in Scotland.

From a chemical analysis, by Dr. Penny, of the water distilled from that in Greenock Harbour by this system, on board the ship Orissa, it is found to contain 7 cubic inches of air per imperial gallon. Comparing this with the water as supplied to the inhabitants of towns—in Aberdeen the water has 7·25 cubic inches, and in Perth 6·8 cubic inches in the same quantity. Loch Katrine water has 8·25 cubic inches per imperial gallon. The average of several of the other principal towns in Scotland is about the same as the water distilled from sea-water by this apparatus.

FIG. 1.

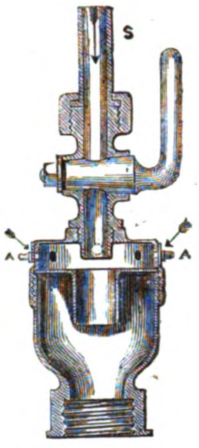


FIG. 2.

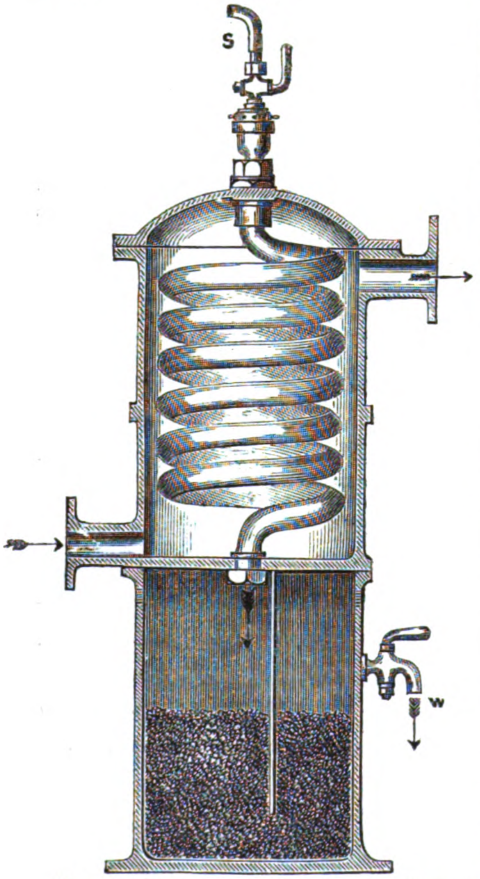

Two distil-aërators of different sizes were exhibited; and in the discussion which followed—

Dr. Macquorn Rankine asked if Mr. Russell was acquainted with Dr. Normandy's apparatus for distilling water?

Mr. Russell was acquainted with its general features, but could not give a detailed description.

Mr. James R. Napier said he had seen Dr. Normandy's apparatus at work, but this was a much simpler arrangement. The water he tasted from Dr. Normandy's apparatus, if not passed through charcoal, was quite oily and undrinkable; but after passing through the charcoal filter it was excellent. Dr. Normandy stated that the charcoal filter was of little use unless the water was aërated. He believed this little apparatus of Mr. Russell's would be very valuable. He had been told by the eminent shipowner, Mr. Henry Green, that formerly when they carried Coolies they had always a great many deaths every voyage; but after getting Dr. Normandy's apparatus the deaths were very greatly reduced. For emigrant ships, therefore, such an apparatus as that of Mr. Russell must be very valuable. Dr. Normandy's apparatus would, with the same fuel, produce twice as much distilled water as the common distilling apparatus, such as that to which Mr. Russell had shown the application of his aërator. The adaptation of apparatus similar to Gifford's injector or Thomson's jet pump for aërating the water, was very ingenious.

Mr. Russell said that they had found very little difference with or without charcoal.

Dr. Macquorn Rankine said he believed that was mainly determined by the kind of water distilled. If there was no organic matter in the water, then it was not absolutely necessary to filter it through charcoal.

Mr. James R. Napier said that sailors of the steamer Lancefield, during one of her voyages to the West Highlands, were under the necessity of drinking the condensed steam from the cylinder jacket without any filtering. Some of them fancied it was bad; but he himself did not find it disagreeable, and it had not an oily taste.

Mr. Downie remarked that one of the peculiarities of this apparatus was, that it was applicable to distilling apparatus of any kind, and it looked as if it would be of little cost, and hence the value of its application.

Mr. Russell, in answer to questions, said it could be applied to any apparatus for distilling water, such as the steam pipe in the paddle-box of a steamer, and in any position. Ten gallons of fresh water an hour could be obtained from the smaller distil-aërator exhibited, the condenser for which was 1 ft. in diameter; by the larger 40 gallons could be got in the hour. It worked at any pressure. There was no objection to letting in any quantity of air, as any superfluous air was discharged with the distilled water. Those who had inquired as to the cost of the apparatus he must refer to Messrs. Alex. Chaplin and Co., Cranstonhill, Glasgow, who were manufacturing the distil-aërators and condensers.

Mr. Brownlie said it had been remarked that it might be used as a condenser for anything; but this was not quite accurate, as it would not do for spirits, as a large amount of them would go away with the air.

Mr. Gilchrist said that in Messrs. Allan's boats Normandy's apparatus had been fitted up, but was a little troublesome to keep in order. This, however, looked very simple. Normandy's also was very expensive, and this looked much less so.

Dr. Macquorn Rankine remarked that a number of the members had expressed their sense of the merit of this contrivance. He thought it must be obvious to every one, how efficient and how easily managed this apparatus would be.

After the last meeting of the Institution of Civil Engineers, a model of a railway break was exhibited by Mr. W. G. Creamer, of New York. This plan was stated to embrace—first, an arrangement of compensating, or balanced breaks, actuated by one lever, and distributing the pressure equally on all the wheels, with a small expenditure of power; secondly, an attachment of reserved power to the breaks of every carriage, in combination with a non-elastic signal rope, so as to enable the driver instantly to apply every break in case of danger; or, on the separation of the train, or any part being thrown from the line, the breaks would apply themselves automatically, as each carriage was entirely independent of all the others, and the breaks were available wherever they were placed in the train.

Meetings for the Week.

MON.—*British Architects*, at 8 p.m.
Royal Geographical Soc., "Explorations in Australia," by Messrs. Stuart, Landsborough, and McKinlay, at 8.30 p.m.
Medical, at 8.30 p.m.
London Inst., "On Music," by J. Pottman, Esq., at 7 p.m.
TUES.—*Royal Inst.*, "On Animal Mechanics," by Prof. Marshall, at 3 p.m.
WED.—*Soc. of Arts*, "On the Influence of Social Institutions upon the Progress of Art in this and Foreign Countries," by G. R. Burnell, Esq., at 8 p.m.
London Inst., "On the Zoology of Warm-blooded Vertebrata," by C. C. Blake, Esq., at 7 p.m.
THUR.—*Antiquarians*, at 8.30 p.m.
Royal Inst, "On Chemical Affinity," by Dr. Frankland, at 3 p.m.
Royal Soc., at 8.30 p.m.
FRI. — *Royal Inst.*, "On Fogs and Fog Signals," by Dr. Gladstone, at 8 p.m.

TO CORRESPONDENTS.

The MECHANICS' MAGAZINE is sent post-free to subscribers of £1 1s. 8d. yearly, or 10s. 10d. half-yearly, payable in advance. Post orders made payable to Mr. R. A. Brooman, of 166, Fleet-street, E.C.

Advertisements are inserted in the MECHANICS' MAGAZINE at the rate of 6d. per line, or 5½d per line for 6 insertions, 5d. per line for 13 insertions, 4½d. for 26 insertions, and 4d. a line for 52 insertions. Each line consists of about 10 words. Woodcuts are charged at the same rate as type. Special arrangements made for large advertisments.

To insure insertion in the following number, advertisments should reach the office not later than 5 o'clock on Thursday evening.

No notice can be taken of anonymous communications. Whatever is intended for insertion must be authenticated by the name and address of the writer; not necessarily for publication, but as a guarantee of his good faith.

RECEIVED.—Capt. Norton—J. M.—F. F.—J. R. T.—L. S.—W. B.—Messrs. B. & Co.—C. B. A.—D. & Sons.

T. P.—(Manchester). Thanks.

B. L.—You had best advertise.

A. F. B.—We know of no work on the subject.

KESSEL.—The plate of your boiler ought not to be overheated at the point shown. It is probably too heavily fired.

F. L. P.—Your proposed scheme is absurd. We would strongly advise you to carefully peruse some good work on mechanics.

S. T. (Lincoln).—Send your application, with testimonials, &c., to the Secretary of the Admiralty, Steam Branch, Whitehall.

CATAPULT (Bradford).—The formula given by writers on artillery for calculating the velocity of recoil in ft. per second is $\frac{Vw}{W}$ wherein V is the initial velocity of the shot in ft., w the weight of the shot, and W the weight of the gun with its carriage. It is, however, a remarkable fact that the recoil increases with the elevation of the gun. In the case you put to us, the recoil would probably be more than 20 ft. A 32-pounder, fired at an elevation of 4 deg., gives a recoil of about 19 ft. on a horizontal platform.

W. W. (Portsmouth.—We fear that you must be very inexperienced if you think that the bringing out of any new scheme for "marine propulsion" would "commemorate the great event of the Royal Union," or could be "made to share in our national honours." There are nearly 4,000 patents taken out every year, only 3½ per cent. of which are prolonged to the full extent of the 14 years. Do you think that your invention is one of the grains of wheat in this annual mass of chaff?

W. F. (Caldy, South Wales).—You will find in one of the stanzas of the "Ancient Mariner," written by S. T. Coleridge nearly 50 years ago, the complete idea of the "Pneumatic Despatch." You might have had a similar idea "more than 20 years ago," but there is a great distance between an idea and its practical realization. The engineers of the Pneumatic Despatch Company are Messrs. Rammell and Clarke. Mr. Latimer Clarke is the patentee of the apparatus.

Correspondence.

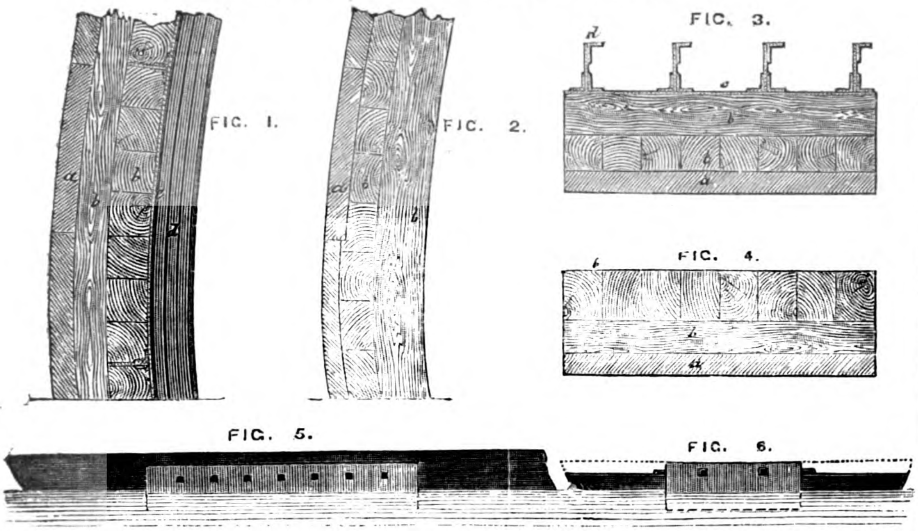
COMBUSTIBLE IRON-CLADS.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE.

SIR,—My last letter was written some days before the debates on the Navy Estimates. It questioned the conduct and motives of the Admiralty in appointing Mr. Reed over the heads of experienced and talented master shipwrights, and in contemplating the construction of a fleet of combustible iron-clads. It is, in my mind, impossible to separate the appointment and the proposal, and



SECTIONS OF THE "DEFENCE" AND "ENTERPRISE."

I am glad to find that members so competent to arrive at sound conclusions as Sir John Pakington, Sir Frederick Smith, Mr. Cobden, Mr. Laird, and Sir S. M. Peto take the same view of those questions as that which I presented to your readers. The whole matter is in good hands; and there is little danger of the men of wood, with the aid, even of Mr. Reed, carrying their point. After the suspension of the resolution for the construction of wooden iron-clads, I should say no more on the subject, were I not well acquainted with the dogged determination at Whitehall to carry that project into execution; I, therefore, think it may be of service to the cause of iron to illustrate, with diagrams, the principle of Mr. Reed's system, as well as the comparative force of resistance of an iron and a wooden iron-cased hull.

These sketches represent sections of the "Defence" and "Enterprise," both partially protected on the plan of the "Warrior." They refer only to the armour-plating and fighting-box, and not to the design of the vessels. Figs. 1 and 3 are sections of the broadside of the "Warrior," which is similar to that of the "Defence." *a*, the armour plate, 4½ in. thick; *b*, teak backing, 18 in.; *c*, iron skin; *d*, iron frames. Figs. 2 and 4 are corresponding sections of the broadside of the "Enterprise," which Mr. Reed calls a belt, as if it were some new conception of his own; but it is nothing more than the armour-plated portion of the hull from under the water-line to the gunwale, *a* being the armour plate, 4½ inches thick, diminishing to 3 inches at the bows and stern; *b*, the wooden hull, 18 inches thick. The difference between the two systems is simply that the iron skin and the iron frames, or ribs, marked *c d*, on Figs. 1 and 3, which form the hull of the iron ship and constitute the chief element of rigidity and strength to resist projectiles, are totally wanting in the hull of the wooden ship (Figs. 2 and 4). The latter, in fact, possesses only the strength of the armour plates and backing (*a b*) of the former. It will be seen at a glance how vastly inferior in force of resistance to the impact of shot the side of the "Enterprise" is to that of the "Defence" or "Warrior." The bulge formed at the back of an armour plate by a shot, which does not penetrate, will drive splinters from a wooden hull between decks, an effect which an iron hull effectually prevents.

In testing plates on the sides of wooden ships at Portsmouth that result is constantly produced; whilst the iron skin and frames of the "Warrior" section, in the experiments at Shoeburyness, not only opposed an impassable barrier to 68 and 110-pounders, but arrested the passage of the Armstrong 150-pounder shot, after they had penetrated the armour plate and backing. In the event of the armour plate being penetrated with incendiary projectiles, of which the Whitworth shell has proved the practicability, the hull of the "Enterprise" would be in flames; but if the wood backing of the "Warrior" were ignited, there would still be a wall of iron for the protection of the interior of the vessel, and the fire might be extinguished. Fig 5 is a sketch of the broadside of the "Defence," and Fig 6 of that of the "Enterprise." The object of these diagrams is to show that Mr. Reed's battery is, in principle, an imitation of the "Warrior" or "Defence" fighting-box. The central portion of the gun-deck, equal to about one-half the length of the ship, is armour-plated at the broadsides, and separated from the ends by bulkheads athwartship, which are also armour-plated. The difference in the build is that the gun-deck of the "Warrior" and "Defence" is continued from the bulkheads to the stem and stern, but without the sides being armour-plated; whilst the upper works of the "Enterprise," at the bows and skin, are so arranged, that, when in fighting trim she can point her guns fore and aft through ports in the athwartship bulkheads. Her armament will consist of four 110-pounder guns, two of which can be fought on each broadside, or through ports pierced in the armour-plated bulkheads fore and aft. She is pierced for eight guns, and carries four. The sea-going properties and speed of this vessel cannot be determined until she has been tried at sea. Considering her light draught and the weight she will carry above the load-line in broadside and battery armour and armament, she may be top-heavy, and roll and pitch considerably, in which case the manner in which she is constructed fore and aft will expose her to ship heavy seas, and make her anything but a dry sea-boat.

It is singular with what pertinacity the Admiralty assumes, that, serviceable vessels of the smaller classes cannot be built of iron. Doubtless, the wish is father to the thought; and we must suppose they don't wish to build them, and will not abandon wood except by compulsion. It is a fact, that Mr. Reed's original design of an "Enterprise," was for an iron vessel; but the plan did not, in that material, find favour in the Comptroller's department. It was not until Mr. Reed modified his design and contrived the ingenious device of a "wooden-bottom with iron top-sides," that he became the man of the situation. The stores of timber were accumulated in the dockyards, and the shipwrights were out of work. There was a plethora of wood, and no employment for labour. Mr. Reed came to the rescue, and we know the result. But he committed a fatal blunder. The most valuable characteristic of an iron ship is incombustibility—immunity from destruction by incendiary shells. In designing "wooden-bottoms," he sacrificed the essential condition of an iron-clad. Enough on this subject. Honest members are attentive to the moves of the game. The Admiralty are checkmated, and not likely to carry out their intention of building wooden ships.

CIVILIAN.

THE CHIEF CONSTRUCTOR OF THE NAVY.

SIR,—A great deal has been said in and out of the House of Commons on Mr. Reed's appointment as Chief Constructor of the Navy. The appointment has been condemned, because Mr. Reed has been lifted over the heads of other and older men, and because the time-honoured arrangement of promotion by seniority has been disregarded. Now, I know nothing of Mr. Reed beyond that he is an acknowledged scientific authority on naval construction, and that he has in whatever he has undertaken exhibited considerable energy. But I imagine that his Grace the Duke of Somerset has reasons for believing that Mr. Reed possesses qualities fitting him for the post. For years past, our public writers and economical reformers have been stating that the public interests have been sacrificed to red-tape; that men have been appointed to offices for which they were particularly disqualified; that old men have occupied posts that required the energy of young men to worthily fill; that square men have been put into round holes; that the circumlocution-office of the Admiralty and other departments is a disgrace to us as a nation; and that we required a revolution in the manner of doing our national business. These and similar things have been said again and again, until we are tired of hearing them. Besides, all acknowledge that the statements are true. Well, the Duke of Somerset has apparently taken the advice which has been so plentifully offered, and selected a man for an important post without consulting the "old fogies" and "time-honoured arrangements." He did not ask whether Mr. Reed had been so many years in the service, whether he had been stuffed full of experiences of the last century; but he selected Mr. Reed because he thought he was the best man for the work to be done, and I think, as an outsider, that he deserves credit for such a courageous exercise of power. Mind, I am not saying whether Mr. Reed is or is not qualified for the duties imposed upon him by his new office. I assume that he is qualified, and if so, I hope the Government will be uninfluenced by the carpings of small critics, whether in the Parliament or the press.

I am, &c.,
A CORNISHMAN.

PRESSURE GAUGES.

SIR,—In the notice of the report of the "Association for the Prevention of Steam Boiler Explosions, &c." in your impression of the 20th inst., I observe some remarks on the four kinds of pressure gauges in general use—viz., the mercurial column, the mercurial differential gauge, the dial gauge, and the compressed air gauge. For high pressures the two former kinds of gauge are impracticable. The dial gauge, consisting principally of a metallic spring, loses its accuracy by continued working, and is often very difficult, if not impossible, to repair and adjust. The compressed air gaunge is unfavourably mentioned in the report as one "in which a syphon column of mercury as a piston acts upon an air cushion, and is found to be universally incorrect, and quite unworthy of confidence." I believe these faults to be indisputable with reference to the above described construction of compressed air gauge.

A compressed air gauge, the patented invention of Mr. Alexander Allan, of Perth, has been in extensive use during the last three years, and with the most satisfactory result. It consists of a pillar of brass, having within it a chamber of peculiar form, in order to give equal divisions on the graduated scale of the gauge. This chamber is connected, by passages at top and bottom, with a glass tube. The exact quantity of air necessary for its correct working is measured from a cock at the bottom of the gauge. Instead of mercury, water is used in this gauge, and pressure is indicated by the surface of the water in the glass tube forming an index to the graduated scale engraved on the polished exterior of the brass pillar.

Perth, Feb. 26, 1863. J. M.

MR. REED'S SHIPS.

SIR,—The increasing employment of iron in shipbuilding indicates undoubtedly great and beneficial progress in the art, and yet I cannot think it wise and reasonable to denounce the construction of wooden vessels universally, although your correspondent "Civilian" encouraged me by his example to do so. This is mere partizanship, and not judicious advocacy. Surely, the advantages belonging to wood which "Civilian" very fairly cites—the speed which the capability of being coppered materially tends to produce and to perpetuate, and the superior strength of the ship's bottom as against local injuries from grounding in shallow waters, or from striking against sunken rocks or coral reefs in comparatively unknown seas—are paramount reasons why our ships of war of the lighter class should be built of wood. And especially are these reasons enforced, when we consider that the commanders of these vessels must necessarily be venturesome in the execution of daring enterprises, and that they are called upon to do lengthened service in all parts of the world, where ports in which, to refit or even to clear away the weeds and barnacles, which are the pests of iron ships, are not to be found.

Surely, considerations of comparative economy cannot be allowed to compete in importance with the efficiency of vessels often engaged in services where objects of high political interest, or even the national welfare, may be at stake.

Now, whether ships of this class—such as the "Enterprise" and the "Favourite," which Mr. E. J. Reed, the chief constructor of the navy, has designed, and being about 1,000 and 2,000 tons, with two and four years respectively—can be made invulnerable, or at least as little vulnerable as the "Warrior," is a distinct question from that of the material with which they are built; and if these ships fail in the matter of defence, or in their general efficiency as cruisers, it will not be because in the main they are wooden vessels, but because it is attempted to unite in them qualities which, to any valuable amount, are in truth incompatible with each other for all ships below, say 4,000 tons. There is, avowedly, a compromise of sterling properties in these vessels; speed and coal carrying capacity on the one hand, and efficient armour defence on the other, are sacrificed to a considerable extent each for the other. Lord Clarence Paget declared in the House of Commons that it was not shot but shell that it was hoped they would repel; and Mr. Reed announced at the outset that it was not intended they should be swift vessels. It is not necessary, therefore, that as to the matter of defence, their mode of construction should be subjected to "the target trial for the settlement of this point," as suggested by "Civilian." The point is not in dispute, it is a compromise. No ship built wholly of iron which your correspondent could devise, though defended with armour of unusual thickness, supported by his wonder-working "rigidity of iron framing," could stand the test, and at the same time possess sea-going qualities worth having, the condition to be observed being this, that the tonnage of his vessel shall not be greater than that of the "Enterprise." We can no more compass impossibilities with iron than with leather; it will not suffice for everything.*

Let me not, however, be supposed to impute blame to Mr. Reed and his "*enterprise.*" His ingenious attempt to do what he can in the way of compromise for the class of vessels which he has taken in hand is very praiseworthy, and the experiment is well worth making for the sake of seeing how much can be effected on that principle. He will have a solid, compact shell of resistance in his hull, and more capable at a distance of withstanding the concussion, even of heavy shot, than "Civilian," I imagine, would allow, although certainly liable to *penetration* at close quarters, even from a 68-pounder. A defence consisting wholly of iron would not, in my opinion, resist concussion equally well, supposing its weight to be the same. Such vessels must keep their distance, and depend upon their own ordnance being of longer range and of greater weight in the projectile. They must keep their distance if they can, for speed is power; but, unfortunately, they will not be able to do much in this way through steaming; they must depend greatly on sailing properties, and accordingly Mr. Reed has, it is said, given to them beautiful swift going forms, but whether with a special view to their being powerfully rigged I do not know. A small iron-clad, with little speed, is a helpless thing on the water, and by no means the lion among lambs, in a contest with larger wooden vessels, which Mr. Cobden imagines it to be. With plenty of sea-room they would run it down before it could do much mischief. For harbour defence—if taking up positions upon the shoals—such vessels would certainly be very efficient. But sea-going properties and powers, including in the latter great steam resources both in engines and coals, appear to me to be paramount qualities for a roaming light-craft cruiser, and that a great deal of what is now considered indispensable for defence, whether it be in iron or in wood, might in this case be wisely sacrificed to obtain them. At any rate, I would only place armour upon a semicircular bulwark across such a vessel, and at some distance from the bow, taking care to fight her stem on, in which position, nevertheless, the whole of her armanent (two guns) would be employed.

I speak with some confidence of the impossibility of combining the full sea-going properties and powers, which a steam cruiser of the class of sloops and corvettes ought to have, with the iron and wooden defence of the "Warrior," in like proportional extent of surface; for having last year sent you two preliminary letters, describing in general terms the form and mode of construction of a vessel by which I hoped to approximate at least towards a solution of this problem, I subsequently set to work upon the drudgery of calculation for all the details, the result of which was, that wishing to limit my displacement to 2,000 tons, and to facilitate speed by fixing the proportion of breadth to length in the ratio of 1 to 9 (30 ft. wide 270 ft. long), I found I could not impart what I thought sufficient stability to my ship, by reason of the immense top weight of the armour, armament, &c. Notwithstanding many variations, the centre of gravity would persist in appearing too much above the line of floatation to please me, and the metacentre would obstinately come below the centre, instead of above it. This unstable equilibrium, although partially in the abstract—inasmuch as it depended only on the hull armour and armament, apart from any counterpoise in the weight and stowage of ballast, engines, and coals—did not appear to me to be the right thing, however slightingly some marine architects would perhaps have considered it. The great evil of the present day in our ships of war, and especially in our iron-clads, is their rolling—the "Warrior" lately rolling 30 degrees, so it is reported—and though this question belongs to dynamics, and that of equilibrium to statics, yet there is a connection between them, and I was desirous, above all things, of giving my guns a steady platform. By the bye, Mr. Scott Russell is reported to have said in one of his lectures, that the centre of gravity of the "Warrior" is 6 ft. above the water-line. Can this be correct? How much higher, then, can the metacentre be? Well, in addition to this awkward state of affairs, I found I could not put into the hold of my vessel that amount in weight (though enough to restore a certain degree of stability) of engines and coals which I deemed requisite for sea-going efficiency, although I would have been satisfied with a probable speed of 14 knots an hour. And yet my project rested upon the principle that only one-third (90 ft.) of the vessel's length should appear above water and want armouring, along with a portion of this part of the hull, requiring protection below the water-line; the remaining portion, amounting to more than three-fourths of the displacement, being supposed to be sufficiently defended from shot by being submerged. How such a vessel, extending 90 ft. under water, beyond the stem, and the same beyond the stern, would behave in heavy seas, I cannot pretend to say. However, such was my principle, and, although involving little surface to cover with armour, I found it to be impossible to combine the requisite speed with invulnerability on such a moderate scale of displacement. And here I would remark, that a light craft, carrying two guns amidships and as heavy pieces of ordnance as you like, is just that sort of vessel which requires speed the most, in order to render it efficient as a war ship, whether for offence or defence, or for running away. Speed is power: and here, in my opinion, it is the supreme consideration, and therefore I have now given up the idea of making such a vessel invulnerable; and to this conclusion, I think, the Admiralty also will come in due time. In the mean while, it will be very proper to experiment with Mr. Reed's ships, but not to rush headlong into a great expenditure in that direction. On this point "Civilian" and myself will agree. But the public must not be disappointed if Mr. Reed's ships do not steam more than 7 or 8 knots an hour, for that is about the speed, I believe, which, at the utmost, he has promised. That he will be able to do so much, and carry sufficient coals to keep it up for a few days, is a great feat, and a very clever thing.

I am, &c.,

BENJN. CHEVERTON.

PATENT LAW REFORM.

SIR,—I beg to resume the subject of "Patent Law Reform" in your journal. Allusion to some matters of machinery in the prosecution of a patent, may, I think, be useful to your readers. The present rules which regulate the term and extension of a patent, appear to me to be reasonably and fairly subject to any suggestions your correspondents may have to make. It is not, I think, likely, that either the one or the other will be extended. There is clearly an indisposition to extend the monopoly of patentees, which I think it desirable to impress on your readers.

The "provisional specification" is at present, as is generally known, of a very doubtful character. I need scarcely say that the value of a patent is dependent on its sufficiency. The Government is generally prepared in haste to satisfy what I may call the "eagerness" of our inventor. Its terms are intentionally *elastic* and *pliable*, and no doubt to some extent these are necessary and indispensable incidents. Human actions in every department of life are, and can only be, mere approximations to perfection, which alone is but a tribute of certainty. It seems to me as the result of my own observation and experience, that it will be but to dispense with what are known as "claims." If this be so, the "provisional specification" should simply consist of a representation of the invention, the whole of which, it might be understood, is claimed as a *combination*. This, I suggest, for the consideration of your readers.

Now, Sir, as to the "complete specification;" this, as we know, is intended to disclose the details of the invention *in extenso*. This document ought to be so clear and explicit, that an ordinary machinist could, with the aid of the drawings, make a like machine. Why should not the original specification be sufficient? It really seems to me that the document in question might advantageously be sufficient for all purposes. The adoption of one specification would at least relcive the perplexing questions which are constantly arising under the the present system. Allow me to urge the consideration of your readers to this subject, as one which involves no small expenses, both in its *preparation* and *consequences*. The "claiming clauses" which are commonly introduced into the document, almost invariably fail to accomplish their object. More than this, it is a well-understood principle by lawyers, that the "second specification" cannot enlarge the first, so that the latter has to be read and expended by the former. This is a stringent rule of construction, since inventors commonly endeavour to vary or improve the mechanism on the results of subsequent observation or discovery. What are your readers' views on this question.

Let me, in conclusion, add one *suggestion* with the specification, and this I can make without any supposition of personal interest. It is desirable that the specification in all cases should be prepared or settled by professional machinists, and that a liberal remuneration should be given. These documents surely depend, not upon their *length* or *complexity*, but upon their *accuracy* and *simplicity*. I ventured to press this caution on your readers attention.

I am, &c.,

J. CULVERHOUSE.

3, Compton-street, Ballspond,
Feb. 23, 1863.

WEAKNESS OF CAST-IRON.

SIR,—A very interesting illustration of the weakness of cast-iron, when subject to a sudden strain, is now attracting public attention opposite the Horse Guards. A cast-iron girder, to form the outer girder of the bridge for the new line of railway at Balham, was being transported to that place from the Great Western Railway. It was about 36 ft. long, and 3 ft. deep, with top and bottom flanges 6 in. wide. The iron about 1¼ in. thick.

It was laid upon the "trolly," or truck, upon its side, with its hinder end near the ground, and its front end projecting over the front of the truck. The two bearings on the truck being about 12 ft. from each end, and 12 ft. apart. On arriving at the place above mentioned, a sudden jolt on the stones caused the overhanging piece, weighing rather more than a ton, to snap off as though it had been glass. By the merest accident the girder lay somewhat obliquely, and the piece fell just clear of the horses.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

SIR,—I have been a subscriber to your MAGAZINE from its commencement, August, 1823, and you have published many letters from me on various subjects, for which I thank you. I have, in this instance, to ask a favour by your inserting the following letter, which has been refused as an advertisement in the *Engineer* newspaper. I have been frequently attacked by that journal, and they have as fre-

---

* Literary gentlemen are too often apt to think that they are competent to write on any subject. A ludicrous instance, however, of their occasional incapacity occurred the other day in "our own correspondent's" communication to his daily paper, in which, lamenting the continued employment of wood and hemp instead of iron in Devonport dockyard, he observed that, "The suspension of this stupendous and superfluous rope-making would at least be felt beneficially in the *linen* trade, because just now the demand for *linen* is extremely active." No doubt this gentleman could have written equally well for our entertainment, if not for our instruction, about armour plates and shipbuilding.

quently refused to insert my replies, thus leaving the public to believe that what they had stated were facts.

Yours respectfully,
J. Hopkinson.

[Advertisement.]

To the Editor of the "Engineer."

Sir,—I beg to inform you that the fourth edition of my treatise, "The Steam Engine Explained by the Use of the Indicator," is just published, and the price is 2s. 6d.; it contains practical explanations on valve setting, compounding, and expansion, together with rules and tables for the management of the steam-engine, boiler, &c. I anticipate the same onslaught upon this edition as you passed upon my third edition, and write to prepare your readers for the attack. It has, as you previously remarked, again "*extended itself*," having now upwards of 400 pages, and illustrated by 100 wood-cuts and engravings. Should you again criticize, I hope you will give me an Englishman's right, by inserting my reply, which was refused me on the last occasion.

Apparently, my third edition has been of great value to you in answering some of your correspondents, and I trust this edition may be of further use by supplying you with practical facts and examples derived from experience, not in the office, but in company with the steam-engine.

I remain, yours respectfully,
J. Hopkinson, Engineer.
Britannia Works, Huddersfield.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

The Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

Steam Engines, &c., 2188, 2226, 2240.
Boilers and Furnaces, 2213, 2251.
Roads and Vehicles, including railway plant and carriages, saddlery and harness, &c., 2181, 2185, 2202, 2223, 2230, 2231, 2242, 2243.
Ships and Boats, including their fittings, 2190, 2205, 2208, 2214, 2215, 2216, 2221.
Cultivation of the Soil, including agricultural implements and machines, 2218.
Food and Beverages, including apparatus for preparing food for men and animals, 2194, 2199, 2217, 2219, 2220.
Fibrous Fabrics, including machinery for treating fibres, pulp, paper, &c., 2189, 2192, 2197, 2198, 2200, 2203, 2204, 2211, 2227, 2229, 2237, 2241, 2247.
Buildings and Building Materials—*none*.
Lighting, Heating, and Ventilating, 2174, 2178, 2182, 2206, 2212, 2234.
Furniture and Apparel, including household utensils, time-keepers, jewellery, musical instruments, &c., 2173, 2184, 2187, 2195, 2207, 2222, 2232, 2236, 2245, 2250.
Metals, including apparatus for their manufacture, 2175, 2191, 2253, 2254.
Chemistry and Photography—*none*.
Electrical Apparatus, 2238.
Warfare, 2180, 2186, 2210, 2224, 2239.
Letter-Press Printing—*none*.
Miscellaneous, 2172, 2176, 2177, 2179, 2183, 2193, 2196, 2201, 2209, 2225, 2228, 2233, 2235, 2244, 2246, 2249, 2252, 2255.

2172. J. Ransom and E. Ransom. *Improvements in mounting millstones.* Dated July 31, 1862.

This consists in a method of connecting millstones with the impelling shaft or spindle, so as readily and conveniently to adjust and preserve the parallelism of the stones. For this purpose the centre of the mace which impels the runner is mortised to fit on the head of the spindle; from this central mace proceed three or more equi-distant arms extending to the outside of the stone, eye, or other sufficient length. A flange rises on each side of these arms, forming a groove to receive the arms of the centre iron. Screws pass through these flanges, their points pressing against the arms of the centre iron, and propelling the stone. In the under side of the centre iron, which carries the runner, a hollow is sunk to receive the the top of the spindle on which it rests. The arms of the centre iron extend beyond the eye into the body of the stone, in which they are firmly fixed. A screw passes perpendicularly through each arm, and its extremity rests on the corresponding arm of the mace. By means of these screws (or by wedges) the parallelism of the runner and bed stone can be adjusted and preserved. *Patent completed.*

2173. C. Bedells. *Improvements in the manufacture of braces.* Dated July 31, 1862.

This invention consists in the manufacture of braces from loop-formed fabrics, such as are produced in knitting and warp machinery. The braces are formed of two thicknesses of the material cemented together. *Patent completed.*

2174. G. T. Bousfield. *Improvements in the manufacture of fluids suitable for burning in lamps, and for other uses.* (A communication.) Dated July 31, 1862.

The patentee claims the compound produced by the combination of the mineral oils with fusel oil, the said compound constituting a new manufacture. He also claims the compound produced by the combination of naptha with alcohol and fusel oil, the said compound constituting a new manufacture. He also claims the heavy liquid obtained by treating the combination of petroleum (or kerosine) and fusel oil with alcohol, the said heavy liquid constituting a new manufacture. *Patent completed.*

2175. A. V. Newton. *Improved machinery for planing metal.* (A communication.) Dated July 31, 1862.

This consists in furnishing the table of the machine with a rack of an ordinary construction, and in operating this rack by a worm or screw, which enables the driving shaft to cross the bed diagonally, passing out in a position near enough to the upright which carries the slide rest and cutting tool, to enable the driving belt to be within reach of the operator. And it also consists in a peculiar mode of transmitting and arresting motion by a ratchet, which must be the driver, and a double pawl attached to the object to be driven, so that while retained in gear with the ratchet motion will be imparted to the object to be driven, until, by the interposition of a suitable stop, the continuous motion of the ratchet will lift the pawl out of gear. It consists also in providing this pawl with a suitable projection, having upon it a friction, which shall always be in contact with the driver, so that when the motion of the driver is reversed the friction pad will reverse the position of the pawl, and cause it to present its other end to the ratchet, which is thus enabled to move it in the opposite direction, until the pawl is again lifted out of gear by the interposition of a suitable stop, as before; also in controlling the position of the two belts which impart motion to the machine in opposite directions by the segment of an internal and external wheel, working about a common centre, and having one tooth on each gearing, into a corresponding tooth on each belt shifter; so that a full movement of the segment in either direction will operate the belt shifters, but not at the same time, one being arranged to complete its movement before the other commences, and upon reversing the motion of the segments the movement of the shifters will take place as before, but in the reverse order, that is, the shifter which completed its movement last will commence, and complete its movements first, whenever the segments are moved in the opposite direction. *Patent completed.*

2176. W. E. Newton. *Improvements in lubricating compounds.* (A communication.) Dated July 31, 1862.

This consists in the production of a lubricating compound or fluid composed of coal oil obtained in a natural state, or simply by artificial distillation, combined with caoutchouc, and with or without the addition of water. *Patent completed.*

2177. J. List. *An improved means for obtaining distances and heights, and distances between distant objects, without computation.* Dated August 1, 1862.

This consists of, 1, an instrument made of wood and brass, with hinges to fold into a suitable size for carrying in the pocket. When in use it is opened out in the form of a square; it is provided with two small foresights, and a back sight hinged to a moveable slide; a small stand with a socket connects it to a rifle when piled, or to a common tripod. For taking the quantity of an angle a line of tangent divisions (the radius being 20 in.) is marked on the sliding part, and also above it on the fixed part; on the other or lower part there are proportional divisions, with numbers to indicate at sight the distance of an object. There is also a table of figures for giving the height or distance between two objects at a distance, according to the number of degrees and minutes subtended in the observations. An extended scale is also provided to show more accurately the long distances; 2, The instrument in the form of a drawing board, or table top, is applicable for ships of war, and is made to ship and tranship for putting away when not required; it is provided with bearings for a telescope, in addition to the other sights, so that the common sights and telescope can be used at pleasure. *Patent abandoned.*

2178. J. Sinclair. *Improved arrangements for ventilating, and in part applicable for fumigating.* Dated August 1, 1862.

A modification of these improved arrangements, suitable for a dwelling house, for example, comprises in the first place apparatus for admitting fresh air from without into the hall or lobby. Provision for this may be made by an opening in any part of the wall; it is, however, most convenient to contrive this at the top of the door. For this purpose a recess may be cut or formed in the lintel to receive an air duct of a rectangular or other convenient form; or the duct may project downwards from the lintel, and a recess be cut out of the top edge of the door to fit it; or, again, it may be fixed to the top of the door. The outer end of the air duct is open for the air to enter, and at the inner end it communicates with a shallow vertical box, the side or sides of which are perforated to cause the air to enter in a diffused condition, and without perceptible draught. Similar apparatus for the ingress of air is provided at the doors of the various rooms communicating with the hall or lobby. The modification of the improved arrangements suitable for ventilating potato mounds, corn ricks, and the like, comprises apparatus made, by preference, in sections or lengths, which can be combined to suit various sizes of mounds or ricks. A section of the apparatus consists of a rectangular box of convenient length, divided by a partition into two ducts. The bottom duct is for the egress of vapour or vitiated air, which enters it by perforations in the bottom and sides, and leaves it at either end. The upper duct is for the inlet of fresh air, which enters at either end, and is diffused amongst the vegetables or grain through perforations in the top and sides. *Patent abandoned.*

2179. D. T. Lee. *Improvements in ornamenting surfaces of wood and of papier mache.* Dated August 1, 1862.

In ornamenting a surface of wood, according to this invention, the inventor takes a piece of veneer, and by means of the process called saw piercing or fret cutting, he cuts or pierces in the said veneer all those parts of the ornament which on the surface to be ornamented are to be sunken or depressed. He attaches the pierced veneer by means of glue to the surface to be ornamented, and afterwards polishes the surface of the veneer. There is thus produced an ornament on the surface of the wood which has the appearance of a carving on a flat or plain surface. The surface to which the pierced veneer is glued or attached may be matted or wrought before or after the veneer is affixed to it, so as thereby to produce a closer resemblance to carving from the flat. In ornamenting surfaces of papier mache, he proceeds in the manner described with reference to wood, excepting that he attaches pierced veneers of papier mache to the papier mache to be ornamented, and finishes the ornamental surface by the processes ordinarily employed for finishing surfaces of papier mache. *Patent abandoned.*

2180. G. Haseltine. *Improvements in apparatus for drying grain, gunpowder, &c.* (A communication.) Dated August 1, 1862.

This apparatus consists of a hollow cylinder, or its equivalent, provided with self-opening and closing valves, or their equivalents, for the transmission of air. It is hung upon a horizontal shaft, and is rotated by the application of any convenient power for the purpose. The patentee claims the rotating cylinder, or its equivalent receptacle, for containing and keeping in motion the material acted on, when the same is provided with a valve or valves, or an equivalent arrangement, for the transmission of air for ventilating, and for the passage of the vapour evolved, substantially as described. *Patent completed.*

2181. G. A. Biddell. *Improvements in railway crossings.* Dated August 1, 1862.

These improvements have reference to the construction and manufacture of chilled cast iron railway crossings, for which letters patent were granted to the present patentee, bearing date 19th September, 1855 (No. 2113). The patentee claims preventing the chilling action taking place quite up to the extreme ends or point of the upper wearing surface of the crossings, so as to form the parts, which have been found liable to chip and break off, less brittle, more tough, and much less liable to chip or break than when chilled at those parts as heretofore. *Patent completed.*

2182. J. C. Onions. *Improvements in portable forges.* Dated August 1, 1862.

This invention consists in the employment of a fan for creating the blast, and in the arrangement of the parts hereafter described. The patentee places the fan under the hearth, and at the back end of the forge, and leads the blast up into the fuel through a bent tuyere or pipe, in which the upper part of the fan case is made to terminate. He places the chest or box for holding tools within the frame of the forge, and below the hearth. He gives motion to the fan by belts passed over pulleys driven by a crank handle, or by toothed gear. *Patent completed.*

2183. R. and D. Nurse. *An improved annealing pot.* Dated August 1, 1862.

This invention consists in employing wrought-iron instead of cast-iron in the manufacture of annealing pots, and also in making the pot double—that is to say, as two cases, one fitting into the other. By these means the metal will expand and contract without sustaining injury, and the air will be effectually excluded from the plates therein. *Patent completed.*

2184. J. E. Marsh. *Improvements in the construction of metal rivets used in joining or securing together parts of boots, shoes, and other articles of leather, and also in machinery for making such rivets.* Dated August 1, 1862.

In carrying out this invention, the patentee makes the points of the rivets flat, with two sides only, or what are termed chisel pointed, or as nearly approaching this form as possible. Thus made, the point has sufficient strength to allow of its being clenched. The improvements in machinery for making these rivets consist in the alteration of the cutters, which require to be sunk to the form necessary to produce the flat point. *Patent completed.*

2185. C. H. Plevens and H. Rider. *Improvements in the construction of colliery waggons, tubs, or corves, and in apparatus for tipping or discharging the same.* Dated August 1, 1862.

This invention consists in the employment of an end door, hung and fastened in a peculiar manner, which allows the door, by a self-acting arrangement, to be raised and released from its lower fastenings, the pressure of the coal against the door causing it to swing outwards, and the door being at the same time raised, as above stated, the free discharge of even the largest coal is obtained. *Patent completed.*

2186. W. E. Newton. *Improvements in projectiles for ordnance and small arms, and in the wads or sabots to be used therewith.* (A communication.) Dated August 1, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2187. T. G. Webb. *Improvements in the manufacture of flint glass.* Dated August 1, 1862.

This invention has for its object a reduction of the expense of manufacturing flint glass, with which view the patentee uses sulphate or muriate of potash, in place of or in combination with the carbonate commonly employed. *Patent completed.*

2188. T. Onion. *Improvements in rotary steam-engines, and in propellers adapted to propelling vessels in water.* Dated August 2, 1862.

In the specification of letters patent granted to the present patentee, dated the 21st day of January, 1847 (No. 11,539), he described a rotary engine with a revolving piston in a stationary case, having two rings, or vanes, upon which the steam alternately acted to produce rotary motion to the main shaft, upon which the revolving piston was fixed, there being a single abutment with an inlet or outlet passage on each side thereof. But, by such arrangement, it has been found that the pressure exerted by the steam on the parts as they rotate is unequal, which, when applying such engine to the purpose of propelling, is especially prejudicial, and an object of the first part of the present improvements is to remedy this evil. For this purpose, he applies two abutments and two inlet and outlet passages for the steam on opposite sides of the case, and he employs four sliding vanes, or wings, to the revolving piston, by which the effect of the pressure of the steam, as well as of the exhaust, will be always acting equally on opposite sides of the shaft. He also gives additional support to the wings, or vanes, to lessen friction on their surfaces as they move to and from their axis, by causing them to slide in flanges, or projections, at the ends of the rotating piston in the case. As screw propellers are at present arranged, the water is acted upon and thrown off therefrom when they are in motion at an angle to the line of the shaft, and the direction of motion of the vessel, which is found materially to interfere with the correct action of the steering apparatus. To remedy this evil, according to the second part of this invention, he applies a flange, or flanges, standing out from the face of such propellers, to cause the water, in their rotation, to be thrown off them in a line corresponding with that of the propeller shaft, or directly opposite to the direction of motion of the vessel, by which the rudder will have free action on the water, in either direction, for the proper steering of the vessel, whilst a considerable advantage will also be gained in counteracting the slip through the water. *Patent completed.*

2189. J. Briggs. *Improvements in the manufacture of belts, webs, braids, tapes, laces, and other similar articles produced by weaving, plaiting, or twisting.* Dated August 2, 1862.

This invention relates to such articles as belts, webs, braids, laces, tapes, bindings, and other similar articles known in the trade as small wares, and consists in manufacturing such articles with a figured surface, the designs or patterns to be obtained by printing either one or both sides with engraved cylinders, in contra-distinction to producing such patterns by means of jacquard weaving and by block printing. *Patent completed.*

2190. J. Gray. *Improved means or arrangements for cleaning ships' bottoms, and for preventing the fouling thereof.* Dated August 2, 1862.

This invention is founded on the well-known fact that, when the asteroida, mollusca, and cirrhopæda (which are the kinds of shell fish usually found upon ships' bottoms), at first attach themselves to the ship's bottom, they are in a soft gelatinous state, and can be easily scraped or brushed off, whereas if they are allowed to remain a little while they become encased in hard shells, and so firmly fixed as to require very considerable force to remove them. Similarly seaweeds and other adhering matters are much more slightly fixed and more easily removable when only freshly attached than afterwards. This said invention consists in taking advantage of these circumstances by cleaning the ship's bottom continuously, or at short intervals, and in providing conveniently available means for affixing such continuous or intermittent cleaning, either whilst the ship is sailing, or whilst it is in port. *Patent completed.*

2191. E. B. Wilson and M. Picard. *Improvements in the manufacture of iron and steel.* Dated August 2, 1862.

The object of this invention is to run molten iron or steel directly from a converting vessel, mounted on trunnions (or otherwise capable of a rotating motion) in which it has been produced, into moulds, or into receivers placed over the moulds. The form of the receivers is such as will admit of the metal entering the moulds under a very slight pressure, and is so arranged as to facilitate the removal of the scoria floating on the surface of the metal. *Patent abandoned.*

2192. C. Warne. *Improvements in the manufacture of linen drabbett.* Dated August 2, 1862.

This invention consists in manufacturing drabbett of flax warp and flax weft. The advantage of using this flax warp and flax weft combined, instead of flax and cotton, is that it is much more durable and stronger. This material is dyed drab, olive, slate, or other suitable colours. *Patent abandoned.*

2193. G. Coles, J. A. Jaques, and J. A. Fanshawe. *Improvements in the manufacture of grinding and polishing tools and surfaces.* Dated August 2, 1862.

This invention relates, in the first place, to a mode of producing such articles by a combination of pulverized gritty or cutting ingredients, with a preparation of oxydized or other oil and sulphur, with or without the addition of resinous, gummy, mucilaginous, or albuminous matters. In carrying out this part of the invention, the patentees use either emery, pulverized glass, fine granulated iron, or fine iron or steel filings or borings, or other hard cutting substances reduced to a finely-divided state, and they mix these substances in combination with any suitable oil and resinous, bituminous, or gummy matter, or mucilaginous or albuminous matters (in some cases with the addition of sulphur or sulphurets), taking care that all the ingredients be well mixed or incoporated, so that the whole mass may be brought as near as possible to a homogeneous state. Secondly, in combining fine steel or other hard wire with any suitable plastic material, such as that above mentioned, so as to produce a cutting surface like a file or rasp. *Patent completed.*

2194. A. and E. M. Denny. *Improvements in the manufacture of bacon.* Dated August 4, 1862.

This invention relates to the mode of keeping the pickling liquor used for curing bacon at an even temperature, without emptying the vessel in which it is contained, and thus avoiding exposure of the meat or dead carcasses of the pigs to atmospheric influences; also the bacon is more evenly cured than by the process now adopted, by which it is subjected to many variations of temperature. The invention consists in drawing off the liquor at or near the bottom of the vessel containing the meat, and passing it through layers of ice, or ice and salt, or, if preferred, through a coil of pipes placed in a refrigerator or in ice. The liquor being thus reduced in temperature, it is run on the top of the vessel, thus keeping up a circulating current of cool pickle through the pickling vessel. This current is continued until the proper temperature is obtained. The taking off and running on of the liquor may be done by pumps or other suitable contrivance. *Patent completed.*

2195. S. Simon. *An improvement in ornamenting ladies' and children's slippers.* Dated August 5, 1862.

This invention consists in cutting, stamping, or otherwise perforating any ornamental designs out of the fronts of the uppers of ladies' and children's slippers, and fixing a piece of different-coloured leather at the back of the same, so as to show through the perforations. *Patent abandoned.*

2196. J. Thomas. *An improved self-adjusting screw wrench.* Dated August 5, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2197. J. Higgin. *An improved substitute for cow-dung, used in printing and dyeing textile fabrics or yarns.* Dated August 5, 1862.

The patentee has discovered that certain alkaline salts, namely, the tungstates and molybdates, may be used for neutralizing acid phosphates and arseniates without any insoluble compound being precipitated, and, consequently, without any loss or waste of phosphoric or arsenic acid. The compound salts thus produced forms a convenient substitute for cow-dung in the dunging process, without the disadvantages found inseparable from the old phosphate of lime and soda. *Patent completed.*

2198. J. Townsend. *Improvements in damping cotton and other fibrous materials and fabrics, in preserving the same from mildew, and in preserving size or stiffening from decomposition.* Dated August 5, 1862,

This invention has for its object to prevent the inconvenience occurring when cotton or other fibrous materials or fabrics are damped or stiffened in the ordinary way. And the said invention consists in applying chloride of magnesium, chloride of calcium, or a mixture of both, to the fibrous material, either prior or subsequently to its being woven. *Patent completed.*

2199. W. Clark. *Improvements in the purification of water, and in apparatus employed therein.* (A communication.) Dated August 5, 1862.

The patentee claims—1, The improved method of ascertaining the proportions of lime necessary for the purification of different calcareous waters, by means of the instrument described, and which the patentee terms a hydro-calcemeter, by which alone this improved purifying process can be rendered generally practicable. 2, The application of this improved instrument, or hydro-calcemeter, for registering the amount of carbonic acid or carbonates, or for measuring the caustic power of different kinds of lime. 3, The application of this improved system of purification for the extraction and utilization of precipitate, either natural or contained in other matters, such as carbonic acid, or sulphate of lime, or they may be reduced to lime and again rendered suitable for the purification of water, or for other purposes, in the manner described. *Patent completed.*

2200. M. J. Roberts. *Improvements in means or apparatus for spinning and preparing wool and other fibrous substances.* Dated August 5, 1862.

The object of these improvements is—1, To obtain a better drag to the thread, or yarn, whilst being wound on to the bobbins in preparing or spinning fibrous substances. For this purpose, whilst the flyer has motion given to it by a band, as is well understood, and the bobbin is capable of being drawn round by the act of winding thereon, such motion to the bobbin is retarded by its friction on a spindle, the lower surface of the bobbin resting on a supporting base carried by the spindle, and by adjustable, weighted, or other pressure, applied to such spindle. Or the bobbin may be fixed upon the spindle, and the spindle retarded, as before mentioned. But, in all cases, the inventor makes the spindle to be driven by the flyer, or the flyer by the spindle, so that one may partake of all the inequalities of motion of the other. The invention relates—2, To the use of a shield, or protector, applied to flyers in spinning and preparing frames, for the purpose of preventing entanglement of the fibres of yarn proceeding from the delivering rollers with those of the yarn upon the bobbin where such yarn is wound on. *Patent abandoned.*

2201. J. R. Nicholl. *Improved means of, and apparatus for, utilizing and disposing of the sewage of towns and villages.* Dated August 5, 1862.

In carrying out this invention, the inventor proposes to employ the natural porosity of the soil—where such is available—for disposing of the fluid portion of the filtration, having previously brought the sewage to the proper condition for filtering rapidly through the soil. He lengthens the sewer, or sewers, which have been, or may be, formed by the addition of two, three, four, or more diverging channels, which, from their extended surface, will cause a sluggish flow of the sewage. Each of these diverging channels he fits with sluice valves, which permit of the discharge, at suitable periods of the sewage, into removable tanks. Before escaping from these tanks, the fluid will have to pass through a filtering sieve, or strainer, and continue its onward course in the sewer; or it may, if need be, be passed through a second and finer strainer. The sewage, flowing very slowly through the tanks, will leave a continually accumulating deposit in them, and, when any one of them is full, its sluice valve is to be closed. A heavy lid, fitting into the tank, or other pressure, may be applied for expressing the remaining fluid from the tank, suitable perforations being made therein for admitting of the discharge of the fluid. The filled tank is now to be removed, and another substituted in its place, to restore the communication between the detached parts of the sewer. *Patent abandoned.*

2202. A. Priestley. *Improvements in arrangements or apparatus applicable to locomotive railway engines and carriages for distributing sand upon the rails to give adhesion to the driving and brake wheels of such engines and carriages.* Dated August 5, 1862.

The object of this invention is, that coarse, wet, stony, or clayey sand may be used (but coarse wet sand in preference), and delivered on to the rails with certainty in a continuous and uniform layer when required. The invention consists in the use of agitators and screws or equivalent mechanism, which are placed in a box or hopper containing sand, which agitators and screws receive continous motion when required from the axle of the wheel, or the periphery of the wheel of the engine or carriage to which the apparatus is applied, so that the sand is uniformly delivered when required from the box or hopper, and is conducted down a pipe to the front of the wheels to which adhesion is to be given. *Patent completed.*

2203. W. W. Burdon. *Improvements in reducing wood fibres to pulp.* Dated August 6, 1862.

This invention consists in the use of fixed stones, rasps, or other like reducing agents, and in passing blocks or pieces of wood across the grain or fibre thereof, over and upon such stones or reducing agents. The patentee employs water to assist the reduction of the fibre, and to carry off the pulpy mass. Or he reduces the wood to pulp by rubbing stones upon wood across the grain thereof. In some cases he finds it advantageous to soften the wood by steam, or by boiling in water, or in an alkaline solution. *Patent completed.*

2204. J. C. Richardson. *An improvement or improvements in cleaning cotton waste.* Dated August 6, 1862.

In order to effect the cleaning of the said cotton waste, the inventor first boils it in a strong solution of common soda or caustic soda, or other alkaline solution. He boils the cotton waste in the said solution during six or eight hours. He next steeps the cotton waste in dilute sulphuric acid for six or eight hours. The acid he employs consists of a mixture of one part by volume of commercial oil of vitriol to 30 parts by volume of water. He afterwards washes the cotton waste in water, and again boils it for about six hours in a dilute solution of soda, or in other alkaline solution. He finally washes the cotton waste in water, and then dries it in a stove, or allows it to dry by the spontaneous evaporation of the water remaining in it after the greater part of the water has been pressed or squeezed out of it. *Patent abandoned.*

2205. M. C. Sinibaldi. *Improvements in the manufacture of chains, and in the apparatus employed therein.* Dated August 6, 1862.

For the purposes of this invention the links are cast of suitable metal, and the succeeding links are, in the act of casting, caused to link one within the other. A series of metal moulds are employed, and they are formed, arranged, and connected together to produce alternately the horizontal and vertical links. Each mould is, by preference, formed to have a single link cast therein, and the series of moulds are placed or connected together in such manner that the melted metal run into one mould does not enter or mix with the metal which is run into the other mould or moulds used therewith; on the contrary, the succeeding links of a chain, whether cast in succession or simultaneously in a series of moulds, are separate castings, and are, by the act of casting, linked one in another. In this manner may any desired number of moulds be used, and each have a link cast therein, and, by reason of the forms of the moulds, and their being used together, the succeeding links will, when cast, be linked into each other. *Patent abandoned.*

2206. W. G. Valentin and F. Levick. *Improvements in the generation of combustible gases for lighting and heating purposes, and in the mode of applying such gases to the manufacture of iron, glass, and other processes in the arts where great heat is required.* Dated August 6, 1862.

This invention consists in an improved mode of obtaining combustible gases from the decomposition of water and carbonaceous matters. The generation of hydrogen gas by the decomposition of water into its two elements, hydrogen and oxygen, has long been known, but great difficulty has been hitherto experienced in effecting the desired object in an economical and regular manner, and especially in obtaining hydrogen sufficiently carburetted to admit of its being usefully employed also for lighting purposes. This invention consists in passing steam (either common or superheated steam, but by preference the latter) through a mass of incandescent fuel, such as coal, coke, or charcoal, by which means the steam will be decomposed, and the hydrogen will be set free, and a part thereof will combine with a small portion of carbon, thereby producing carburetted hydrogen, while the oxygen will combine with another portion of the carbon and produce carbonic oxide, together with smaller or larger quantities of carbonic acid, according to the manner in which the decomposition of the steam is carried out. This gaseous mixture or mixed gases will be found to possess a high degree of heating power when burnt with air, and may be employed for various heating purposes, such as melting, refining, puddling, and heating iron. As the passage of steam through incandescent carbon will greatly reduce its temperature, and will, in fact, finally extinguish or stop the combustion whenever the point is reached where the temperature of the incandescent carbon falls below the temperature at which the decomposition of steam by carbon into carbonic oxide and hydrogen can take place, it is necessary to keep up the temperature by heating the retorts from the outside. *Patent completed.*

2207. F. Nauheim. *An improvement in the ornamenting of boots, shoes, and goloshes,* Dated August 6, 1862.

This invention relates to the ornamenting of the uppers or parts of the uppers of dress boots and shoes, and also goloshes when formed of enamelled leather. The ornament which the inventor proposes to adopt may consist of any appropriate device, the effect being obtained by removing the gloss from the leather at the part where the ornament occurs, the glossy surface remaining to form the back ground. This dulling of the surface may be effected in various ways. *Patent abandoned.*

2208. J. H. Johnson. *Improvements in the construction of armour plates for ships and forts, and applicable to other like purposes.* (A communication.) Dated August 6, 1862.

This invention consists in making armour plates of several laminæ, but in lieu of connecting the whole of such plates together by bolts passing through the entire series, it is proposed to couple only the contiguous ones; thus—if four plates or laminæ be employed, No. 1 will be bolted, rivetted, or otherwise secured to No. 3, which, in its turn, is similarly secured to No. 3, this plate being secured to No. 4 plate, and so on throughout any desired number of plates. *Patent completed.*

2209. M. A. F. Mennons. *An improved self-inking hand-stamp.* (A communication.) Dated August 7, 1862.

This invention consists in a self-inking stamp combining the stamp or die, and the inking pad. The die turns on itself in raising or descending the interior of the apparatus, and thus presents its face alternately to the inking pad, and to the article which is to receive the impression. The inking pad and ink reservoir are placed in the upper part of the interior of the apparatus, but so that the hand of operator is not in immediate contact with the part in which they are contained. The invention cannot be fully described without reference to the drawings. *Patent completed.*

2210. C. Culling. *Improvements in fire-arms.* Dated August 7, 1862.

To render fire-arms less liable to be discharged by accident, apparatus is, according to the invention, applied to a fire-arm in such manner as to hold or retain the hammer or trigger, or parts interposed between them, so that the fire-arm shall not be discharged till the cheek of the person using the fire-arm is pressed on to the stock in the act of looking along the barrel or barrels in taking aim. With this object a cheek rest or cushion is applied to that part of a stock of a fire-arm against which the cheek of the person when aiming is pressed; the rest or cushion is constantly pressed outwards by the action of a spring, and is in connection with a bolt, catch, or detent, which acts on and retains the hammer or trigger, or other parts of the lock, from movement, until the rest or cushion is depressed by the cheek pressing upon it, and then the motion of the rest or cushion is communicated to the bolt, catch, or detent, which moves so as to leave the lock free to act. The rest or cushion is fixed to a rod or to the end of a lever which passes into the interior of the stock, and such rod or lever is connected with the bolt, catch, or detent, by suitable connecting rods or parts. Upon the butt-plate or other parts of the work is, or are fixed, one or more bolts, balls, or catches, so that in a loading position the action is made void until brought into a horizontal aiming position, when the bolt, ball, or catch, will fall and allow the gun to be discharged by the pressure from the shoulder, and pulling the trigger. When applied to rifles, the cheek rest or cushion may be made adjustable, so as to be easily raised and adapted to the height of the sight, according to the range which may be required; and in this case the rest is made of wood or metal connected by a steel or metal slide to the raising sight on the barrels, so that, when shooting at a short distance, the rest is let in flush with the stock; the sight is also flat upon the barrel. By raising the sight for any distance, the action causes the rest to rise in the same proportion from the stock, so that the cheek rests upon it as upon the stock shooting at short distances. *Patent abandoned.*

2211. A. Thiriez. *A new machine for glossing and glazing all thready fabrics.* Dated August 7, 1862.

This invention is not described apart from the drawings. *Patent abandoned.*

2212. F. H. M. O. D. O. de Finis de Lacombe. *Improvements in the means of lighting towns.* Dated August 7, 1862.

The patentee claims making atmospheric air subservient as a means for lighting towns or other localities, or the dwellings thereof, by causing the said air to pass through or come in contact with any suitable volatile liquid hydro-carbon, so as to become sufficiently impregnated with the volatile parts of the said hydro-carbon for allowing the air thus impregnated to be ignited and burned by suitable burners, provision being made in the mains, pipes, or other fittings, by proper branch pipes or other suitable means, for allowing to convey into the town or other locality, or the dwellings thereof, fresh, pure, or cool air, for ventilating or cooling the same, whereas this air if properly heated may also serve for warming the same. *Patent completed.*

2213. J. H. Johnson. *Improvements in blast furnaces.* (A communication.) Dated August 7, 1862.

This invention relates to the adaptation to blast furnaces of a peculiar arrangement of apparatus or means for collecting and utilizing the otherwise waste gases which ordinarily escape from the mouth or top of the furnace. According to this invention, a circular or other shaped metal hopper or casing is placed inside the throat of the furnace, and extends a short distance down the same, having an annular space or chamber all round between the outer side of the hopper and the inner side of the throat of the furnace. The gases pass into this annular chamber, and are conducted therefrom to any locality where they are to be used, by suitable conduits or passages opening directly into the annular chamber above referred to. The hopper is connected in any convenient way to a cast-iron plate forming the crown of the furnace, such plate having an annular water-gutter constructed thereon for the purpose of forming a hydraulic joint for the reception of a lip or edge of a dome-shaped metal cover, which entirely closes the mouth of the furnace, but is so formed and disposed as to leave an annular opening between the top edge or lip of the hopper and the inner side or wall of the gutter, to allow a portion of the gases to pass freely over the edge of the hopper, and down into the annular chamber first referred to, suitable stops or valves being placed, if desired, in the openings leading to the chamber below, for the purpose of regulating the draught or passage of the gas. By this system the gases are collected equally from all parts of the transverse section of the furnace, one portion passing over the upper lip or edge of the hopper, and then downwards into the annular chamber, and the other portion passing directly upwards into the annular chamber, entering it at the bottom by passing under the lower lip or edge of the hopper. A weighted lever working on a swivel fulcrum may be used for elevating and removing the cover when required. *Patent abandoned.*

2214. R. A. Brooman. *Improvements in ships and vessels, in order to prevent injury from collisions.* (A communication.) Dated August 7, 1862.

This invention consists in placing from the bow to the stern of the ship or vessel (like a belt) a plate or plates of iron, steel, or other similar material, about 10 in. in width, more or less, and about 5 in. in depth or thickness, more or less, at the centre of each plate. Where the ship or vessel is large, and the main or upper deck is high above the water, the inventor applies another belt or set of plates of iron or steel at the deck next below the main or upper deck. *Patent completed.*

2215. R. A. Brooman. *Improvements in covering ships and vessels built of wood, or iron ships with a backing of wood, before placing iron, steel, or other armour plates on such ships and vessels.* (A communication.) Dated August 7, 1862.

This invention consists in placing india-rubber sheets, or gutta-percha sheets, or other similar material or substance, between the iron, steel, or other armour plates and the wood of such vessel. *Patent completed.*

2216. W. Clark. *Improvements in the rig, spars, and sails of ships and other vessels.* (A communication.) Dated August 7, 1862.

The principal objects of this invention are to reduce the cost of the rig, spars, and sails, by a simple construction and arrangement of parts, to obtain increased speed for a vessel by so arranging and applying the sail as to carry a greater area without injuriously straining either the spars or the hull, and to facilitate the working of the sails, and thereby enable a vessel of a given tonnage to be worked by fewer hands. In carrying out the invention, the inventor fits the yards around the mast in such a manner that their axes intersect the axis of the mast, and make one arm of each longer than the other, so that it may carry a longer area of sail on one side than on the other, the portion on one side of or abaft the mast being separate from the portion on the other side or forward of it. The sails and yards thus applied partake in some degree of the character of what are known as square sails, and in some degree the character of what are known as fore and aft sails, and the yards are worked and secured in position by braces in substantially the same manner as the yards and booms of other vessels. He employs in a vessel one, two, or more masts, according to its size, or, as all circumstances considered, may be most desirable; and he employs on each mast the usual or any suitable number of yards, generally preferring to employ as small a number as practicable, as the object is to reduce the height of the masts and sails as much as possible, and compensate for such reduction by an increased width, the arrangement allowing a greater width to be used without those of one mast taking the wind from those of any other; and he proposes generally to dispense with the use of jibs and flying jibs and their booms, and in some cases, with the bowsprit also. The invention cannot be described in detail without reference to the drawings. *Patent completed.*

2217. B. Coombe. *Improvements in apparatus or machinery for cleaning and decorticating wheat and other grain.* Dated August 7, 1862.

In carrying out this invention, the inventor subjects the grain to a severe action between a pair or several pairs of horizontal surfaces or discs, one of each pair of which is stationary, and the other rotating on an axis. These surfaces are roughened or suitably furnished with scrubbers, as may be desired. He disposes one, two, three, or more of the rotating discs on a vertical axis, the one being placed at a suitable distance below the other. The whole is mounted in a suitable framing, and the axis can be raised or lowered at pleasure, so as to approach or separate the scrubbing discs according to the nature of the grain or the treatment it is to be subjected to. The grain to be treated is fed into a hopper in the upper stationary disc, and enters by a hole in the centre thereof. The centrifugal action created by the rotating disc carries the grain towards the periphery, where it escapes, and falls into a cone or hopper of wire-cloth or other perforated material, and is conducted by it to the centre of the next pair of cleaning discs, and so on through the whole series of escapes at the bottom, cleaned as desired. The matters separated from the grain either pass through the perforated material of the hoppers or conducting cones mentioned, or is separated and blown out by a fan, the blast of which takes effect on the scrubbed grain. *Patent abandoned.*

2218. R. W. Ralph. *Certain improvements in, or applicable to reaping machines.* Dated August 7, 1862.

The object of this invention is to obtain an easy and rapid delivery in sheaf for heavy crops, to supersede tipping platforms and other similar appliances which cannot at all times be worked without involving extra labour. This invention is applicable to most of the ordinary reaping machines now in use, without any material alteration of the main framework of such machines. Instead of the platform on which the grain ordinarily falls, the patentee employs a cloth, the front edge of which is attached to or just above the bar carrying the fingers through which the knife works. The near edge of the cloth is attached to a roller, which roller is actuated by a combination of springs and cords, or other suitable mechanical appliances, by which it is advanced to or withdrawn from the finger-bar in a plane at a suitable angle with the ground. As the roller advances, the cloth is wound round it by the action of a coiled spring contained within the roller, causing the roller to revolve. The roller is thus drawn forward until it comes close up to the finger-bar, when the cut corn falls to the ground. The roller is then drawn back either by an attendant pulling a cord wound round another roller in rear of the apparatus, or by the driver putting in gear with the main travelling wheel a friction wheel, to which the cord from its rear roller may be attached. *Patent completed.*

2219. E. Hall. *Improvements in means or apparatus for preparing foreign grain for grinding.* Dated August 8, 1862.

This invention consists in a process of steaming foreign grain, whereby its flinty nature is removed, and the said grain rendered equal to English produce. The means or apparatus consists of a cylinder placed at an incline in suitable framing, with spouts and stoppers for the introduction and delivery of grain, and with pipes and valves, or taps, for the inlet and outlet of steam. Also a rotating winch, or a spindle having a series of arms and wings thereon capable of rotating, is placed within for producing motion or stirring the grain. Or the cylinder may be made to rotate so as to give motion to the grain by having suitable arrangements provided for the inlet and outlet of the steam and grain. *Patent completed.*

2220. J. Siron. *A new beverage used as a cure from several illnesses and distempers.* Dated August 8, 1862.

The liquid forming the subject of this invention will afford almost immediate relief in cases of headache, cramps in the stomach, colic, bruises, cuts, burns, female complaints, diseases of children, such as worms and convulsions, and many other complaints; it will also preserve the air. It is composed of the following parts, culled when at maturity and in possession of all their aroma, both flower and leaf being used, unless one or other be specially indicated—mentha viridis, artemisia foliis primatifivis, hypericum perforatum, lavender spicata, Achillea millefolium, hypericum, juga dæmonium, plantago arenaria, hyssopus officinalis, thymus serpillum thymus vulgaris, tericrium foliis cordatis vindulatis, artemisia absinthium, salvia officinalis, fœniculum, officinale, anethum fœniculum, apium petroselinum, borrago officinalis, lilium candium, flores sambuci, spirea ulmaria, flores tiliæ parvifloræ, flores rosarium centifoliarum, flores citri medicæ, rosmarinus officinalis, verbena officinalis, santonlina, angelica, lytrium salicaria, anthemis pyrethrum. The inventor places the flowers and leaves above enumerated in a glass vase or bottle, mixing them in about equal portions. He then presses them gently down with the hand, and pours upon them as much wine or brandy as will cover them, closes the vase or bottle, and leaves the whole to macerate and steep at an ordinary temperature during thirty days, when he filters, and the liquid is ready for use. *Patent abandoned.*

2221. F. M. Jennings. *A composition for coating ships' bottoms to prevent fouling.* Dated August 8, 1862.

Here the patentee proposes, for coating the bottoms of ships, boats, or buoys, whether of timber, iron, copper, zinc, Muntz's metal, or any kind of sheathing, or coating over any of these, whether or not previously painted, varnished, or otherwise prepared, to use paraffin, Japan wax, bees' wax, the wax of insects, or vegetable waxes, spermaceti or napthaline, or such other hydro-carbons, purified or otherwise, alone or mixed with tallow fats, stearine, or any animal or vegetable fats, common rosin or oil, or any of their constituents. Either of these substances may be used alone, or they may be used when mixed together in any proportions, or one and all of them may be used mixed together with petroleum, pitch, tar, asphaltum, resins, gum resins, rosin, shellac, gutta percha, india-rubber, or other such resinous matters, or any of the oils distilled therefrom. With any or all of the above first-named substances, or their mixtures or combinations with substances afterwards named, he may combine or mix creosote, carbolic acid, or any pyrogenous acid, alcohol, ether, or organic poisonous matter, or any poisonous metal, metallic oxide or salt, or any substance used as paint, either alone or in combination. *Patent completed.*

2222. J. Whipp. *An improved arrangement of apparatus and means for cleaning articles of ornament and jewellery.* Dated August 8, 1862.

This consists in the use of a box, the bottom of which terminates in a wash-leather or other bag, and so arranged that the box may contain the sawdust and bag when not in use. The bag is unfolded and used in combination with the box to polish the articles by shaking them in the sawdust. This combination of box and bag is fitted into a case, with brushes, leather, and rouge, and forms a useful apparatus. *Patent abandoned.*

2223. N. J. Amies. *Certain improvements in the manufacture of bearings, "journals," and "steps," employed in machinery, and for carriage and other axles.* Dated August 8, 1862.

This is designed for the purpose of reducing the friction generally existing between axles or other shafts, and the bearings, journals, or steps in which they revolve, and consists in manufacturing the surfaces of bearings or steps which are subject or exposed to such friction of a composition consisting of animal fibre, plumbago, steatite, caoutchouc or gutta percha, and any resinous gum, animal glue, or size, the proportions being almost immaterial, if the animal fibre be in sufficient excess, the composition being moulded or cut into the regular form. *Patent completed.*

2224. R. A. Brooman. *Improvements in repeating fire-arms.* (A communication.) Dated August 8, 1862.

This consists in the use of a many-chambered slide, made of steel, and set at right angles to the barrel of the gun, and free to slide in a box or carrier. Each chamber carries a separate cartridge, and has nipples and guards to prevent any accidental discharge. There are conical projections or valve seats on the slide which fit into a seat at the rear end of the barrel to secure a gas-tight joint, or the barrel may enter the chamber. For drawing the slide along these is a series of notches formed on the under side thereof, into which spring-catches take, having motion imparted to them by a cam, whereby the chambers are successively brought into a line with the barrel. Motion is given to the slide carrier, spring hammer, and conical spring stop which locks the slide by a set of cams on one shaft and a reciprocating or vibrating lever, and a spring hammer is caused to rise and fall at each rotation of a circular inclined frame. The motions produced by these cams and levers, are—1, The withdrawal of the many-chambered steel slide from and clear of the barrel. 2, Moving it at right angles to the barrel whereby the chambers are made successively to correspond with the barrel. 3, Driving or pushing it up tightly against the barrel, whereby a conical projection is introduced into the rear of the barrel, then withdrawn, and afterwards moved laterally. Several slides may be employed, so that when one is emptied another may be ready for use, and thus a continuous fire maintained. We cannot here quote all the details. *Patent abandoned.*

2225. W. Clark. *Improvements in signalling.* (A communication.) Dated August 8, 1862.

This consists of a universal analytical grammar of signals. The alphabetic transcription of words is replaced by the adoption of signals, and in the complete separation of words from their grammatical elements such as prepositions, adverbs, or other parts of speech. The signal for every word, such as a verb or substantive, and so on, is always the same whatever be the character of the word in the sentence, this character being indicated by a separate signal, which points out the case, gender, number, tense, or mood, and forms the verbs, adjectives, and adverbs, by being added to a substantive. The use of such grammatical signs or signals is thus reduced to a minimum. One single expression is substituted for several synonymous words, the plainest ideas alone being classed under signals. As to the complex ones, they are figured or represented by two or more signals, themselves representing plain ideas. *Patent abandoned.*

2226. E. Humphrys. *Improvements in steam engines.* Dated August 8, 1862.

This relates to that description of steam engines in which two cylinders—a small one, into which the steam first enters, and a large one, in which it is subsequently allowed to expand—are used, and in which the pistons of the cylinders are connected together by a piston-rod passing through the cover, or partition, which separates the small from the large cylinder. The improvements consist in applying a trunk to the large piston, and a suitable connecting rod, as in ordinary trunk engines, to transmit the power from the two pistons to a crank on a shaft or axis. *Patent completed.*

2227. J. Tatham. *Improvements in machinery or apparatus for preparing, spinning, and weaving cotton and other fibrous materials, parts of which improvements are also applicable to other mechanism in which an uniform or variable rotary motion is required.* Dated August 8, 1862.

This refers 1, To drawing rollers of preparing and spinning machinery, the object thereof being the production of a more level yarn, and to enable the patentee to produce the same from fibres of irregular lengths. With this view, he avoids (to a great extent) a drawing action generated at two fixed points, and allows the fibres to be drawn from variable points arising from their own friction or mutual adhesion. To obtain this result he causes the slivers, or other strands, to lap partly around the circumference of one or more of the rollers, such rollers being so arranged as to deliver the material in a regular strand to the front or drawing rollers. This lapping over the surface acts, therefore, as a modified detention, and does not operate upon the fibres by a nipping action, as in the ordinary arrangements, and thus various lengths of fibres are enabled to accommodate themselves to each other, and to enter into combination without a breakage of the longer or a looseness of the shorter. *Patent completed.*

2228. J. Macintosh, *Improvements in obtaining and applying motive power.* Dated August 9. 1862.

This consists in the rapid generation of power by the aid of oxygenous fuel, composed either of coke, coal, and nitrate of soda, or coke and nitrate of potash. In some cases sulphur may be used, or the chloride of potash, and, if desired, put into form with adhesive substances, such as mineral or vegetable pitch, resins, parraffin, gutta percha, caoutchouc, or glue. The prepared fuel is put into closed tubes or furnaces, with valves for the escape of the gaseous products of the combustion, which may be used alone or in combination with steam, air, or other fluids in giving motion to machinery. This oxygenous fuel may be put into ordinary steam boilers, which fuel, when ignited, instantly produces power to give motion to engines, or it may be used for other purposes where power is required as an auxiliary. *Patent abandoned.*

2229. R. Fowler. *An improved manufacture of woven, plaited, knitted, and other fabrics.* Dated August 9, 1862.

This consists in weaving or otherwise plaiting, knitting, or interlacing together threads that are made or composed of a natural gum, as gutta percha, &c., or of a compound of such gum or gums with other gums or ingredients. The gum may be used in the natural or purified state, and it may be dyed, coloured, or otherwise treated to increase its ornamental effect. *Patent abandoned.*

2230. G. Haseltine. *Improvements in carriage wheels.* (A communication.) Dated Aug. 9, 1862.

This relates chiefly to the novel construction of the hub, and peculiar arrangement of the spokes of carriage wheels. The construction of the hub is such that the spokes of the wheel can be arranged in two rows, thus forming a broader base, the spokes being in contact with each other for part of their width, thus filling the entire circle, while at the same time each separate spoke is supported in part, or in whole, upon each side by a metallic mortise. The hub being formed in two parts, and made of metal, enables the inventor, by a screw upon the pipe-box, to compress the spokes edgewise, and thus preserve their position in the wheel, at the same time the desired amount of dish is given to the wheel by the back part of the hub being concave, and the front part convex, where the two parts impinge against the edge of the spokes. By this arrangement the largest possible number of spokes can be introduced, the required amount of dish obtained, and each spoke be supported by a metallic bearing upon either side, and at the inner end upon the pipe. Any shrinking in the spokes causing looseness can be remedied at any time by screwing up the nut that holds the parts together. The wheel is also so constructed that each spoke has a bearing upon the pipe-box. *Patent completed.*

2231. Sir J. S. Lillie. *Improvements in carriage ways and foot ways.* Dated August 9, 1862.

This consists in the construction of carriage ways or foot ways with gutta percha, asphalte, asphalted felt, wood, or other material, or combination of such materials, rendered impervious to water by a solution of caoutchouc, or other solution suitable for that purpose. When such carriage ways are intended for heavy traffic, the patentee causes the same to be studded with metallic bolts, or with bars of iron, or rows of metallic bolts or studs, such rows to be placed transversely or at right angles to the line of traffic, at intervals of not less than 3 in. apart. *Patent completed.*

2232. J. J. H. Gebhardt. *An improved fastening for purses, pocket books, needle books, ladies' companions, instrument cases, and other similar articles.* (A communication.) Dated August 9, 1862.

This fastening is constructed as follows:—In a spring, or in a tongue or plate attached to a spring, is a slot or opening, into which when the fastening is closed a hook, catch, or a recessed indented or notched piece catches or engages. The fastening is opened by applying pressure on the spring by a knob, or equivalent appliance, whereby the part in which is engaged the aforesaid slot or opening is so moved as to liberate the hook, catch, recessed or notched piece, and allow the latter to be drawn therefrom. To close the fastening, the spring is allowed to return to its original position, and the hook or like agent, being introduced into the slot or opening, will engage or catch therein and close the fastening. *Patent completed.*

2233. A. J. Moreau and A. E. Ragon. *Improvements in the mode of, and apparatus for, treating bituminous and carbonaceous substances for the purpose of obtaining the various products, volatile, liquid, and solid, which they contain, and also in the treatment and application of such products.* Dated August 9, 1862.

This invention consists in a mode of treating liquid hydro-carbons whereby they are deprived of their offensive odour, and the lighter and more volatile separated from the heavier portions. The apparatus employed is not described apart from the drawings. *Patent completed.*

2234. A. J. Moreau and A. E. Ragon. *Improvements in the manufacture of gas and coke.* Dated August 9, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2235. T. De la Rue. *Improvements in the manufacture of pigments and writing inks.* Dated August 9, 1862.

The patentee claims the grinding carbon, aniline, waste and other pigments, with glycerine and gum tragacanth, or other gum, as described. Also the use of a solution of saless, and of a solution of gluten or glutinous material in vinegar, in the preparation of inks from pigments as described. *Patent completed.*

2236. T. Bousfield. *Improvements in the manufacture of hat bodies.* (A communication.) Dated August 9, 1862.

This relates to a novel arrangement of apparatus for manufacturing hat bodies, and consists in an inverted perforated cone placed in an exhausted chamber in connection with a picker arrangement for picking and blowing fur for the purpose of facilitating the process of forming hat bodies. *Patent completed.*

2237. H. B. Barlow. *Improvements in machines for weaving, warping, sizing, and dressing.* (A communication.) Dated August 11, 1862.

This consists in giving an oscillating motion to one or more rods by which the warp is divided. This rod is supported on part of the frame of the machine; a lever bears against each end of the rod, and one of these levers is connected by a string or link to an elbow lever with a bell on one arm. When the rod is displaced by any of the warp threads adhering together, the bell is brought into position for being struck by the lay of the loom, or by any other moving part of the machine for weaving, warping, sizing, and dressing to which the improved apparatus is applied. Or, when the rod is displaced, the lever acts on the ordinary stop-rod to move the driving-strap from the fast to the loose pulley. *Patent completed.*

2238. H. Fenton and W. Stubbs. *Improvements in telegraph wires.* Dated August 11, 1862.

This consists in—1, Covering the cones with a thin covering of copper by immersing them in a bath containing a solution of copper, or in any other convenient way, and afterwards applying a coating or coatings of asphalte, black varnish, or of any other like nonconductive substance or substances. *Patent abandoned.*

2239. W. E. Newton. *Improved machinery for compressing powder for cartridges.* (A communication.) Dated August 11, 1862.

This relates to an arrangement of machinery whereby powder may be compressed in moulds, so as to cause the grains to adhere together in the form of cartridges. The machine consists, principally, of a horizontal revolving plate, which carries a series of moulds open at the bottom, and of suitable shape for forming cartridges. These moulds are provided with moveable bottoms, and the plate is rotated by a toothed rack or racks, which gear into teeth cut round its periphery. The revolving mould plate is placed on a table which has a rising and falling motion communicated to it, so as to bring the contents of the moulds under stationary plungers, whereby the powder in the moulds will be first compressed and then discharged from the moulds by being pushed out through the bottom. One of these plungers is adjustable by a screw, so that the extent of its action may be regulated with accuracy by setting it to proper point. It may, therefore, be adjusted to suit cartridges of various sizes. The mould table is raised and lowered by a toggle joint, worked by a crank, which is driven by suitable gearing. *Patent completed.*

2240. J. Goodfellow. *Improvements in steam or water engines.* Dated Aug. 11, 1862.

This relates to improved modes of regulating the supply of steam, or fluid, to the cylinder, and cutting it off at any portion of the stroke. Instead of a stationary lap at each side of the valve, the inventor uses moveable laps connected together, but capable of being adjusted to any required distance apart, according to the power the engine is required to exert. The aforesaid laps are moved to and fro, so as to form an aperture to the port, and cut off at any portion of the stroke, either by the movement of the slide itself, or by a screw cam, or other contrivance. He also uses moveable laps to surface valves in general, so that, by moving the laps, less power is required to work the valve. *Patent abandoned.*

2241. T. Holdsworth and J. Crossley. *Improvements in means, machinery, or apparatus for warping, scouring, sizing, stretching, measuring, cooling, drying, and beaming yarns for weaving.* Dated August 11, 1862.

This consists, generally, in constructing, arranging, and combining machinery or apparatus for effecting the several purposes in one operation, and particularly in arranging the bobbin creels so that a greater number of ends or threads may be warped together than heretofore, by using supports, and by crossing the threads to prevent entanglement betwixt the bobbins and the point or place where the warp is formed. Also in taking the "lays" or "leash" or dividing the warp to form the shed by healds or heddles. Also in having the scouring troughs lined with or formed of galvanized iron, and in applying a hand lever to remove the top squeezing rollers from contact with the bottom ones when desirable in the scouring and sizing parts of the apparatus. The inventors also use rollers to traverse or travel the warp backward and forward to obtain extent of distance betwixt the squeezing rollers and beam for stretching the threads. Also they apply fans for cooling, and steam cylinders for drying the warp after the process of scouring and sizing. They also apply an index plate or indicating apparatus, so as to be actuated by one of the traverse rollers, for measuring the warp as it is passed forward to the beam, and which apparatus may also be made to mark the cutts or lengths of pieces. They also drive the beam by friction plates capable of adjustment to the stretch of tension desirable to be put upon the warp, and the bearings for the beam are so arranged as to be adjustable to the length thereof. *Patent abandoned.*

2242. W. Clark. *An improved carriage for conveying sugar moulds in sugar refineries.* (A communication.) Dated August 11, 1862.

This consists in supporting or retaining the upper parts of the mould by two adjustable horizontal plates attached to the carriage (arranged substantially as described), and also in using, in connection with the said adjustable plates, a fixed frame or plate, provided with inverted conical recesses to receive the tips of the moulds. It further consists in a novel arrangement of a castor wheel, which supports the front part of the carriage, all being so constructed and arranged as to effect the desired end. *Patent completed.*

2243. N. J. Amies. *Improvements in the manufacture of bearings or steps employed in machinery and railway and other carriages, and in a composition to be applied thereto.* Dated August 11, 1862.

This invention is designed for the purpose of dispensing with brass and other expensive metals employed in the manufacture of steps or bearings, and consists in the solution and use of malleable cast iron for the exterior or case, and in filling the interior or parts subject to friction with any well known iron metallic antifrictional composition, or with one consisting of caoutchouc, gutta percha, or other elastic gums, incorporated with plumbago, steatite, or plastic, earthy, or metallic matters, bound together atomically with vegetable or animal gums or size, and in such proportions as when dry to form a hard and solid filling for the aforesaid hollow case. This composition constitutes the second part of the invention, and may also be used for bearings by itself, the chief feature being the combination of the aforesaid ingredients, or other equivalents, to the entire exclusion of all vegetable or animal fibre, such composition exciting less friction, and, consequently, is better adapted for steps or bearings than when fibrous materials are combined therewith. The bearings, journals, or steps are to be cast of malleable cast iron, and formed with cavities or recesses for the filling of the aforesaid composition to be opposed to the frictional surface requiring lubrication, and which may be made of caoutchouc, gutta percha, or other elastic gum, one part; plumbago, steatite, or plastic, earthy, or metallic matter, three parts; and vegetable or animal gum or size, one part; or such other component parts as may be found desirable; but when water or liquid in a heated state has to come into contact with the composition, the patentee prefers to employ a gum called "rhus copallinus" (gum copal), which is better calculated to resist the action of heated liquids. This composition may be employed alone, suitably cast or formed, without the addition of wood or metal. *Patent completed.*

2244. J. Lancelott. *Improvements in the manufacture of ornamental chains from sheet metal.* Dated August 11, 1862.

The object of this invention is to substitute machine for hand labour in the manufacture from sheet metal of ornamental chains, in which differently formed blanks are used, each link of such chain being composed of an outside blank and an inside blank. The outside blank has perforations, the number of which may vary with the pattern, and in forming a chain these perforated portions of the blank must be bent upwards, so as to form a cup; another similar blank must then be placed above it, with its perforations in line with those of the blank beneath. An inside blank, having as many projecting arms as there are perforations in the outer blank, must then be placed in the topmost outside blank, in such a manner that its arms pass through the lower part of the perforations of this topmost outside blank, and the upper part of the perforations of the blank immediately beneath, the top of which must then be slightly closed inwards the better to secure the arms of the top inside blank within its perforations. *Patent completed.*

2245. M. H. Champion. *Self-closing buttons fastening without thread or needles.* Dated August 11, 1862.

These improved buttons are composed of a shank or stem bent at right angles, one end of this stem being pointed so as to penetrate through any sort of cloth or stuff, and the other end attached either to a small disc or to a button of any shape or size. When the shank is soldered to the button itself, the inventor introduces the shank up to the bend or elbow in the cloth through which it penetrates, its point entering a small spring apparatus on the other side of the material, the spring of which presses the elbow of the shank and prevents its withdrawal. When the stem or shank is not soldered to the button itself, it carries a small disc on the extremity which is not pointed, and in this case the point is passed through from the reverse side of the cloth, and passes not into a spring apparatus, as before mentioned, but into an opening in the button itself; this opening is furnished with a spring which prevents the exit of the shank. The stem or shank must always be held fixed between two opposite sides, and the object of the spring, no matter what its form, is always to prevent the point of the stem leaving this hole or sheath. *Patent abandoned.*

2246. W. E. Gedge. *Improvements in the construction of ladders.* (A communication.) Dated August 11, 1862.

This invention consists, under one modification, of a sliding ladder specially adapted for lighting gas lamps. It is formed of two ordinary straight ladders, one being fixed and with grooved uprights, the other moveable with uprights so made as to slide in the grooves of the ladder first mentioned. The movement of the ladders is effected by means of a cord attached to the lowest round of the moveable ladder and passing through a pulley on the topmost round of the fixed ladder. The strong hooks on the top of the uprights of the moveable ladder permit its being attached to the spot which it is desired to attain. This ladder offers the advantage of reaching any desired height without being embarrassing, and it will be found useful for many purposes other than lighting gas lamps. *Patent abandoned.*

2247. J. Combe and J. H. Smallage. *Improvements in the action and arrangement of machines for winding cops, and in apparatus for holding and receiving such cops when used for warps or sewing thread or other purposes.* Dated August 11, 1862.

We cannot here give space to the voluminous details of this invention. *Patent completed.*

2248. H. Donald. *Improvements in machinery for shearing, punching, and rivetting metals.* Dated August 11, 1862.

This invention relates to a previous patent dated 11th April, 1853 (No. 867), and comprises much detail which we cannot quote here. *Patent abandoned.*

2249. A. J. Martin, J. Goss, and J. Bush. *Improvements in apparatus for distillation.* Dated Aug. 11, 1862.

This invention consists of improvements in apparatus for the purpose of distillation of mineral oils, spirits, and other liquids. The appararus consists of a vertical cylindrical chamber of copper closed at the bottom, and having a moveable cap or cover, or head of the required shape, which is secured by nuts and screws, or in any other manner, so as to be rendered air-tight. Through the cap or cover, or through the upper part of the cylindrical chamber, or any part of the case most convenient, a pipe enters, communicating with a reservoir containing the liquid to be distilled. In the interior of the chamber a series of copper pans is fixed, one above the other, from bottom to top of the chamber, and the liquid to be distilled flows from the reservoir through the pipe into the uppermost pan, whence it runs over into the second pan, and so on to the lowest by reason of each pan having an edge or lip turned down so as to allow the liquid to overflow at such edge. Each of these pans has a false bottom, communicating with two vertical pipes, one on each side of the pans. A pipe, running the whole length of the pans, and coming out of the lower part of the still, and supplied with a tap, with branch pipes from the bottom or side of each pan, may, when needed, be added, so as to draw off any residuum remaining in the pans when they have done working. These pipes are furnished with a supply of steam from a boiler, which steam enters one pipe and circulates throughout the series of false bottoms of the pans, and is carried off by an exit-pipe connected to the other vertical steam-pipe, the excess of liquid to be distilled, overflowing the lowermost pan, being carried away by a pipe to a tank or reservoir; it may thence be passed into a second apparatus, its temperature having been increased by the action of the first; or the liquid may remain in the tank or reservoir and be removed when required. *Patent completed.*

2250. R. Gresty. *Improvements in scarfs or cravats.* Dated August 11, 1862.

In carrying out this invention, the inventor proposes covering a piece of card, buckram, or other suitable stiff material with any description of satin, silk, or other material of which scarfs are ordinarily composed, and then crossing two pieces one over the other to form the ends thereof, the interior being padded. The piece of stiff material is hollowed out at top to fit the front of the neck, and it is to be about four or five inches square, or may be oblong, deeper and narrower, to fill up the space or opening of the waistcoat. Thus it will appear that, when it is placed on the breast, it only requires a piece of elastic material to fasten on to or around the shirt button of the neck to keep the cravat up in its position. the top corners thereof passing under the corners of the collar; or in lieu of a piece of elastic a button, buttons, studs, or hooks, may be attached to the back of the cravat and placed in the button-hole of the shirt front, thereby keeping it always in its proper place. *Patent abandoned.*

2251. W. Macnab. *Improvements in steam boilers and in apparatus for feeding the same, and for effecting circulation therein.* Dated August 12, 1862.

This invention relates—1, to internally-flued cylindrical boilers for steam of moderate pressure, and partly to boilers for high pressure the heating surface of which consists principally of tubes with the water inside them. In the improved cylindrical boiler there may be one or two large furnace tubes, the back ends of which open into a combustion chamber communicating with a number of small tubes by which the gases return to a smoke-box at the front. The front mouth or mouths are made to project forward from the main body of the boiler as far as the front of the smoke-box, being surrounded by a kind of annular water space. The gases return from the smoke-box to the back by two or more comparatively large flue tubes traversing the steam space of the boiler. Two or more of such boilers may be conveniently arranged side by side, or one, two or more pairs may be arranged back to back, and communicating with a single central funnel, but having separate combustion chambers, into which provision may be made for introducing air. To give sufficient steam space a cylindrical steam receiver may be laid along the top cavity between the two boilers of each pair, and an additional flue tube may be passed through each receiver. The improved apparatus for feeding boilers and for effecting circulation therein, consists, according to one modification of a steam cylinder directly connected to the piston or bucket of the pump, the parts being proportioned so as not to work at an excessive speed. The motion of the piston is reversed by means of a tumbler movement acting on the valves and reversing them suddenly as each end of the stroke is reached. *Patent abandoned.*

2252. J. Ramsbottom and G. Hacking. *Improvements in machinery or apparatus for measuring and registering the flow of water and other fluids.* Dated August 12, 1862.

This invention consists in applying to water meters swing hinges, partly similar to those used in dry gas meters, to be placed at or near each end of a cylinder or measuring chamber, having rods which pass through stuffing-boxes in the sides or ends. The said rods are to be connected in such a manner that, as the piston, during its motion from end to end of the cylinder or chamber, forces one hinge outwards, the other hinge will, at the same time, be forced or drawn inwards to be, in its turn, similarly acted on by the piston during its return stroke, and from the bar connecting the two hinges the requisite motion will be obtained to actuate the valve and registering apparatus, either by means of a tumbler, or other more direct manner. Or the said bar may be constructed so as to actuate a valve, or the two hinges may be made to serve the purpose of valves, in order to supply fluid to a piston-valve, which may be actuated by the pressure of the fluid. *Patent abandoned.*

2253. J. Dickson. *Improvements in treating zinc ores and solutions of zinc to obtain zinc therefrom.* Dated August 12, 1862.

The usual method of obtaining zinc from its ores is, after the preliminary sorting and washing, to expose the said ores mixed with a carbonaceous matter to a full white heat for many hours, and during that time to slowly distil the zinc from the said ores. By the present method, the inventor first precipitates metallic zinc from aqueous, acid, saline, or alkaline solutions of zinc obtained from the said ores of zinc, either by washing the said ores and then adding them to water, or other suitable solvents, or by treating the said ores at once with suitable acids, alkalies, or salts, and then transmitting a current of voltaic electricity obtained from inexpensive sources of that power through any of the said solutions of zinc, by means of suitable anodes and cathodes unmixed therein, the metallic zinc in this case being precipitated on the said cathode employed. *Patent abandoned.*

2254. J. Dickson. *Improvements in treating ores and solutions of lead to obtain lead therefrom.* Dated August 12, 1862.

In carrying out this invention, according to the first method, the inventor precipitates metallic lead from aqueous, acid, saline, or alkaline solutions of lead obtained from ores of lead, either by washing the said ores, if they require such treatment, and then adding them to aqueous solutions of common salt, or to other suitable solvents. Or the solution of lead used is that which is the product of voltaic batteries in which lead has been used as a positive pole. The solution of lead obtained is heated to a temperature of 212 deg. Fah., and then decomposed by the influence of a current of voltaic electricity derived from inexpensive sources of that power whereby its metallic lead is precipitated or deposited. By the second method, he obtains lead from its ores or from chemical compounds of lead which are sufficiently rich in lead, by subjecting the said ores or compounds in a state of fusion to the action of a current of voltaic electricity, by immersing carbon or other suitable anodes and cathodes into the said fused ores or compounds, and then respectively connecting the said anodes and cathodes with the negative and positive poles of a voltaic battery. *Patent abandoned.*

2255. L. Serbat. *Certain improvements in lubricating machinery.* Dated August 12, 1862.

This invention consists in employing napthaline, either alone or mixed, or combined with other substances; for lubricating parts of machinery. *Patent abandoned.*

PROVISIONAL PROTECTIONS.

Dated Nov. 21, 1862.

3129. W. E. Gedge, 11, Wellington-street, Strand. An improved elastic fastening for gloves. (A communication.)

Dated Jan. 12, 1863.

98. A. I. Mahon, 25, Leinster-square, Rathmines. Improvements in screw and paddle propellers, and a submarine propeller, also applicable to the raising and forcing of water or other fluids.

Dated Jan. 16, 1863.

228. A. Smith, Mauchlin, gentleman. Improvements in certain parts of staples, locks, bolts, latches, and other similar fastenings.

Dated Jan. 30, 1863.

277. J. W. Branford, merchant, March, Cambridge. Improvements in horse-hoes, and in the means of using the same in husbandry.

283. W. E. Gedge, 11, Wellington-street, Strand. Improvements in hair nets. (A communication.)

Dated Feb. 2, 1863.

294. J. Gibson, Heptonstall, Halifax, manufacturer. Improvements in looms for weaving.

Dated Feb. 6, 1863.

334. A. Johnston, Comely Bank, near Edinburgh, gentleman. Improvements in the propulsion of vessels.

336. A. Clark, Staines, carpenter. Improvements in knife-cleaning apparatus.

338. W. Robins, 4, Dame-street, Islington, engineer. Improvements in the construction of fire-lighters, or faggots.

340. R. D. Tivnann, Wordsley Brass Foundry, Stafford. Improvements in holster boxes, or boxes for screws or pins to work in, and in the manufacture thereof.

Dated Feb. 7, 1863.

342. J. Cameron, Hematite Iron Works, Barrow-in-Furness, chemist. Improvements in the manufacture of iron and alloys of iron.

344. J. Mallison, jun., Bolton-le-Moors, yarn agent. Certain improvements in the process and method of dyeing yarns.

346. W. T. Cooper, Tooley-street, rectifying distiller. Improvements in distilling apparatus.

348. W. Clark, 53, Chancery-lane, engineer. Improvements in the application of gas for the preparation of woodwork generally and iron ships, for their better preservation and reception of paint, or other protecting coating, and for disinfecting ships, hospitals, and other places. (A communication.)

350. J. Miller, Glasgow, pottery manufacturer, and W. Struthers, Hamilton, gentleman. Improvements in securing the corks, stoppers, or lids of bottles, jars, and other similar vessels.

352. G. Redrup, Loughborough, brewer. Improvements in machinery for the cutting of shives, bungs, corks, spiles, and vent or other pegs, and also in machinery for manufacturing the knives, or cutters, employed therein; such machinery being also applicable to the manufacture of trenails, and other cylindrical and conical articles.

Dated Feb. 9, 1863.

354. B. Dobson and E. Barlow, Bolton, machine makers. Certain improvements in carding engines. (A communication.)

358. G. Goucher, Worksop, ironfounder, engineer, and machinist. Improvements in regulating the admission of air into the furnaces of steam boilers.

360. W. B. Rooff, 7, Willow-walk, Kentish-town. An improved respirator.

Dated Feb. 10, 1863.

362. T. Hill, Hampton House, Great Warley, brewer. Improvements in the arrangements employed for the protection of markers at rifle butts.

364. M. Wigzell, Strand, Topsham, Devon. Improvements in machinery or apparatus and method to be used in the manufacture of every description of candles, tapers, and other lights.

366. J. F. Bottom, Nottingham, lace dresser. Improvements in the means or apparatus for dressing lace and other fabrics.

Dated Feb. 11, 1863.

368. A. Corneau, Charleville, France, ironfounder. An improved hot air stove.

370. E. T. Hughes, 123, Chancery-lane. Improvements in apparatus for drilling wood, stone, iron, or other materials. (A communication.)

372. D. Radcliffe, Liverpool, plumber. Improvements in valve taps.

376. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in photographic apparatus. (A communication.)

Dated Feb. 12, 1863.

380. E. Kemp, manager, J. Needham, and O. Robinson, overlooker, Ashton-under-Lyne. Certain improvements in self-acting mules for spinning.

381. A. Morton, Arbroath, Forfar, engineer. Improvements in lawn mowing machines.

382. W. Clark, 53, Chancery-lane, engineer. Improvements in the bearing-surfaces of shafts and other axles. (A communication.)

383. S. H. Phillips, Newgate-street. An improved fastening for purses, portmonnaies, pocket books, bags, reticules, and such like purposes.

384. S. Lamb, Whitehall Works, Leeds, engineer and machine maker, and J. Spink, Oxford-road, Sheffield, joiner. Improvements in machinery for tenoning, grooving, sawing, and otherwise cutting wood.

Dated Feb. 13, 1863.

385. G. H. Birkbeck, 34, Southampton-buildings. Improvements in processes or means employed for separating or extracting silver or other metals from lead. (A communication.)

387. W. E. Gedge, 11, Wellington-street, Strand. Improved table apparatus for promoting the comfort of persons at sea. (A communication.)

389. J. F. Spencer, Newcastle-on-Tyne, engineer. Improvements in steam engines.

391. J. Grantham, 31, Nicholas-lane, civil engineer. Improvements in hydraulic presses.

395. J. A. Schlumberger, Golden-square, chemist. Improvements in treating coal tar dead oils, and for producing phenic or carbolic acid. (A communication.)

Dated Feb. 14, 1863.

403. W. Baylis, joiner, Hulme, and T. H. Hopwood, hosier and engineer. Improvements in tongs or forceps for grasping articles out of reach of the hand.

405. J. Lewis, 5, Wych-street, Strand, engineer and model maker. Improvements in driving sewing machines.

407. T. Thorne, Southsea, carpenter. Improved apparatus for disengaging ships' boats.

409. A. J. Fraser, Water-lane, Great Tower-street. Improvements in window furniture or fastenings.

413. J. H. Johnson, 47, Lincoln's-inn-fields, gentleman. Improvements in wrought-iron casements, and in the means for fastening the same, which improvements are also partly applicable to the framework of glass doors, conservatories, and similar structures. (A communication.)

Dated Feb. 16, 1863.

415. J. W. Crossley, Brighouse, York, dyer and finisher. Improvements in press papers, and in the method or means of drying them, or other similar sheets of paper; applicable also for the drying of woven fabrics, yarns, wool, cotton, or other fibrous substances.

417. W. C. McEntee, Birmingham, merchant, and G. and T. Withers, West Bromwich, fireproof safe manufacturers. Improvements in locks.

419. H. Smith, 3, Regent's-park-terrace, Gloucester-gate. Improvements in apparatus for feeding horses.

421. W. Jackson, Liverpool, engineer. Improvements in pumps.

423. S. W. Clough, Stanningley, York, manager. Improvements in signalling on railways.

425. T. Wilkinson, Rathmines, commercial clerk. Improvements in machinery or apparatus for singeing pigs.

Dated Feb. 17, 1863.

427. J. Lee, Church-gate, Leicester. Improvements in ploughs and harrows.

429. W. C. Ford, Brooklyn, New York. An improvement in paddle-wheels.

433. G. Home, Kensall-green. Improvements in projectiles.

435. S. Pluchart, Paris, France, gentleman. A new kind of food for horses.

437. D. Tassin, 30, Rue du Collège, Liège, engineer. Improvements in preventing the explosion of steam boilers.

Dated Feb. 18, 1863.

441. J. Barker and E. Moss, Manchester, engineers. Improvements in portable and stationary crabs or cranes.

443. J. H. Bly, Great Yarmouth, ironmonger. Improvements in cooking stoves.

447. F. J. Reed, 3, Gresham-street. Improvements in apparatus for traversing guns. (A communication.)

449. J. Puntis, Above Bar, Southampton, and G. Cox, Throgmorton-street. Improved appliances for displaying in the open air or indoors illuminated designs, devices, mottoes, or announcements, and in which jets of gas are employed as the illuminating agent.

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

From the *London Gazette*, March. 3, 1863.

2748. A. V. Newton. Evaporating apparatus. (A communication.)

2825. H. L. Emery. Propelling machinery actuated by the application of animal power.

2831. S. Whitham and T. Wright. Manufacture of iron and steel.

2833. C. Clark. Cigar tubes.

2838. G. Haseltine. Manufacturing nails and brads. (A communication.)

2840. C. Tress and F. C. Belhomme. Hats, caps, and bonnets.

2841. G. Clark. Construction, protection, and armament of ships, vessels, and floating batteries, some of which improvements are applicable to land batteries.

2852. W. S. Gamble. Salinometer.

2860. E. H. Carbutt and G. A. Clough. Power hammers.

2862. R. A. Brooman. Tanning. (A communication.)

2865. L. Groux. Manufacture of soap.

2871. G. and W. Lake. Stirrup.

2873. W. Owen. Stoves.

2885. J. H. Johnson. Heating glass furnaces. (A communication.)

2886. H. C. R. Joubert. Music stools, chairs, or seats.

2890. F. L. H. W. Bilnger. Condensation of steam. (A communication.)

2891. J. J. Ridge. Treating certain farinaceous substances.

2892. P. E. Placet. Engraving.

2894. A. Peek. Evaporating saccharine and saline solutions.

2900. E. and A. Tatham. Manufacture of looped fabrics.

2922. F. L. Stott. Warping yarns or thread.

2930. G. Piggott. Punching, shearing, and rivetting sheets or plates of iron and other metals and alloys.

2931. P. Giffard. Air guns and other air-arms.

2937. W. R. Bowditch. Carburetting or naphthalizing gas.

2952. W. Jenkins. Apparatus for cutting coal.

2959. W. E. Newton. Drying grain and other substances. (A communication.)

3011. W. Clark. Utilizing refuse and azoted matters of commerce. (A communication.)

3033. J. Easton, jun., and J. C. Amos. Sawing wood.

3051. J. A. Duntze. Communicating rotary motion to shafts or axles for various purposes. (A communication.)

3174. J. R. Danks, and B. P. and R. P. Walker. Boot and shoe heel and toe tips, and clog irons.

3190. F. Boecke. Sewing or uniting fabrics.

3195. J. F. Delany and J. C. R. Okes. Double-cylinder expansive steam engines,

3252. J. Braddock. Machinery or apparatus for effecting the separation of impurities from the water employed in steam boilers.

3464. A. W. Sleigh. Rendering or making ships and vessels and floating and shore batteries, or ambulant or stationary defences, impenetrable to shot and shell.

241. D. E. Hughes. Apparatus for effecting telegraphic communications.

267. J. Pouncy. Obtaining, transferring, and printing from photographic pictures or images.

313. G. Haseltine. Uniting metallic surfaces. (A communication.)

338. W. Robins. Construction of fire-lighters or faggots.

The full titles of the patents in the above list can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners' office particulars in writing of the objection to the application.

FRENCH & SMITH, Sworn Brokers,
4, Brabant-court, Philpot-lane, E.C.; and at
4, Rumford-place, Liverpool.

On Monday evening last, Capt. Selwyn read a paper before the Inventors' Institute on the Progress of Submarine Telegraphy, especially as regards the various inventions used for the submergence of telegraphic cables. Sir E. Belcher occupied the chair.

The *Times*, Sept. 15, speaking of Benson's Modern and Antique Watches in the Exhibition, says—"As affording the most striking contrast, Mr. Benson shows with these a fresh exhibition of modern watches, with cases made from prize designs at the South Kensington Museum, some of which are fine specimens of engraving."—Chronometers, duplex, lever, horizontal, repeaters, centre seconds, keyless, split seconds, and every description of watch, adapted to all climates. Benson's Illustrated Pamphlet on Watches (free by post for two stamps) contains a short history of watchmaking, with descriptions and prices. It serves as a guide in the purchase of a watch, and enables those who live in Scotland, Ireland, Wales, the Colonies, India, or any part of the world, to select a watch, and have it sent free and safe by post.—J. W. Benson, Prize Medallist, 33 and 34, Ludgate-hill, London. Established 1749.—[Advertisement.]

THE
MECHANICS' MAGAZINE.

LONDON, FRIDAY, MARCH 13, 1863.

VENTILATION OF SHIPS.

One of the subjects brought under the notice of the Institution of Naval Architects at their last meetings, and appearing in the new volume of "Transactions," to which we referred last week, is ventilation.

Shipbuilders, and especially those of the Royal Navy, are just beginning to see the importance of this subject. In the olden times, the only fresh air which got to the orlop decks and holds of men-of-war and Indiamen, was that which found its way through the hatches and down into the dark depths of the ship, when the warm bodies of the men or beasts immured there, raised the temperature of the imprisoned air and favoured its escape.

On the decks, which were sufficiently high above the water to allow side scuttles or ports to be cut, it might be supposed that there would generally be a good current of pure air. But this was by no means the case. In a man-of-war, the lowest of these decks is that commonly allotted for the sleeping accommodation of the crew, and they are confined to this deck. Hammock-screws are placed in the beams overhead, so as to use the whole of the available space, allowing to each man a width of 16 in. The men are thus packed as closely together as negroes in the hold of a slaver. As the hammocks are slung within 2 ft. of the beams, the men breathe through the night the heated air which passes off from their own bodies and lungs. This can hardly fail to be injurious to them even under the most favourable circumstances; as, for example, when the temperature of the external air is 30 or 40 deg. below that of their bodies, in which case the open hatchways would permit a certain amount of circulation of air between the decks.

But the case would often be as follows:—There would be five or six hundred men, often more, suspended thus above the "lower deck" of a line-of-battle ship; the temperature outside the ship 90 deg. and upwards, and consequently no motion of the air between decks. To make matters worse, the ports would all be closed according to the regulations. The coolest part of the ship would be the holds, from which, perhaps, a faint current would ascend through the spaces between the timbers, and then issue through the openings between the beams upon the sleeping deck. This air would, of course, be charged with the foulness generated by the decay of sawdust, chips, and refuse stores, in the fœtid bilge-water.

Such being the facts of the case even now in our own ships, we must not be surprised to learn that low fevers and pulmonary diseases are alarmingly frequent among a class of men whose hardy lives, compulsory regularity of habits and abstemiousness, ought to produce the most robust health.

Very much might have been done in sailing ships to avoid these evils. The overcrowding of the men, for example, was capable of instant remedy, by appropriating the other decks for sleeping accommodation. But the introduction of steam gave at once an enormous ventilating power, which only needed proper direction in order to give the needful circulation of pure air through all parts of the ship.

It is only, however, within the last two or three years that any attempts have been made to effect this most desirable end, either in the Royal Navy or in passenger ships. In men-of-war, there is considerable difficulty in getting sufficient space on the deck, clear of the guns, for hatchways and scuttles, upon the number and extent of which the success of any system of ventilation must largely depend. But in merchant ships, governed by no such restrictions, there is still grave matter of complaint. The Great Eastern, to take a notable example, has no provision whatever for employing her furnaces as ventilators for the ship. She is dependent upon the hatchways and skylights upon the upper deck, and the scuttles in the side for the supply of air to the entire ship.

The steam vessels which carry the mails between Holyhead and Kingstown, and those belonging to the same company which run with passengers and live stock between Dublin and Liverpool, form an exception to the general rule.

The engineer-in-chief to this company, known as the City of Dublin Company, describes, in a Paper which appears in these "Transactions," the methods adopted by him for securing the excellent ventilation which has been noticed by every observant passenger in these vessels.

The frequent necessity to close the hatches in bad weather, when the hold was crowded with cattle or the lower decks with troops, compelled them to adopt some device for creating an artificial current between decks. The first means adopted was a large fan, worked by a belt in connection with the engine. This was not only large and cumbrous, but it failed to give more than very partial relief. The air in the holds in which the cattle were confined was so foul, that the men in charge were frequently unable to keep their lights burning.

Being thus driven to devise some other mode of obtaining fresh air, Mr. Clarke introduced the fan-engine, patented by Schiele and Williams, of Oldham. In this machine, the fan and a small turbine engine are combined, and a steam pipe being led to it from the boilers, a very small supply of steam is found to be sufficient to keep it in efficient work, which it performs quite noiselessly.

In these vessels, a hollow trunk of about 100 square inches in section, is placed at one side under the deck, the entire length of the vessel. In an iron ship, this may be a box-stringer.

With this main trunk smaller ones are connected extending into the holds, each having a wide mouthpiece to collect the noxious vapours which are to be removed.

The main trunk is then connected with the fan-engine, which is placed on deck near the boiler, or in the engine-room, and a 1-in. pipe is led from the boiler to the engine, with a pressure of 10 lbs. of steam or upwards. The waste steam after working the fan-engine passes to the ordinary waste steam pipe on deck. By this means, complete ventilation by exhaustion may be effected.

Mr. Clarke tells us that an attempt was made to discharge the air, drawn off from the hold in which the cattle were confined, into the stoke room, for the purpose of supplying furnaces with air. But this had to be discontinued, as the foul air was too offensive to the firemen.

The engine may also be employed for the propulsion of air. It has been so employed in the Holyhead packets with perfect success; providing a due supply of air to the stoke-rooms and furnaces, and keeping the air in the cabins and store-rooms quite pure.

We are happy to find that the subject is now attracting the attention of the Government. About eighteen months since a committee was appointed by the Admiralty to consider the subject and report upon the best means of providing proper ventilation for ships of war. In some of these, the difficulties are now greatly increased by the necessity for making the sides shot proof, and for reducing the number and size of those ports and scuttles in the sides, which have hitherto done much towards promoting the circulation between decks.

This difficulty has made itself felt in the French iron-cased ships in the Gulf of Mexico; and the defective ventilation in those ships has produced disease among their crews to a most alarming extent.

With proper precautions this may certainly be avoided; and the Admiralty will, we hope, take care that in our iron-cased ships no precaution is neglected.

THE PATENT RIGHT OF FOWLER'S STEAM BALANCE-PLOUGH.

Like the history of cotton and other manufactures, or like that of the steam-engine itself, so is the history of steam-ploughing a record of some 500 successive patents. The admirable indices of Mr. Woodcroft afford the greatest facilities for tracing the progressive development of the applications of practical mechanics, now playing so large a part in modern life. There is the same series of appearances in most of these engineering histories; a number of impracticable schemes, evidently born and expired in the brains of their projectors, form the foundations for later and more rational undertakings. Two of the most successful early attempts at steam-ploughing by means of rope traction, owe their origin to wealthy amateurs—a fact easy to be accounted for, as only a wealthy man could undertake a course of experiments in steam-ploughing. The opponents of patent right often overlook the truth, that practical mechanics is an experimental and tentative scientific art, and that to bring a new mechanical scheme to a successful issue requires a long purse as well as a long head. How many men could be found to spend thousands in gratuitously establishing truths that can only be arrived at by expensive experiments — truths that would merely afford a basis for others to step in and reap what the first experimenters had sown? The partially successful attempts made by the Marquis of Tweeddale and by Lord Willoughby d'Eresby, show how difficult it is to bring new mechanical undertakings to maturity without the fostering influence of the patent laws. A princely fortune was required before the steam-plough could be brought to its present state of development. Even a very rich nobleman must ride his hobby most furiously before he would expend £60,000 to keep it on its legs. Besides, what aid could be expected from capitalists without the hope of some returns in the case of success?

Even genius is powerless without capital, and the courage and foresight to spend the money profitably. One of the most important patents that have conduced to the present success of steam-ploughing owes its origination to two men of great original mechanical ingenuity, but unprovided with the necessary funds for practically working the invention. This patent had to fall into the hands of Mr. John Fowler, a man of capital as well as ingenuity, before it could be brought to maturity. Mr. Fowler had directed his attention for some time to a kindred pursuit to steam-ploughing, having, as early as March 7th and October 17th, 1850, taken out two successive patents for draining ploughs. Both of these inventions are described in the MECHANICS' MAGAZINE—the first in Vol. 53, page 518, the second in Vol. 54, page 337. He was thus practically prepared to solve the problem of steam-ploughing, just as in a more important instance Stephenson was prepared, by years of experiment in locomotive traction, for the great trials on the Manchester and Liverpool Railway. An illustrated account of Fowler's steam-ploughing tackle will be found in Vol. 1, page 395, and a further account in Vol. 2, page 41 (New Series).

Mr. Fowler's inventions are now come to the last stage of most successful and new mechanical undertakings. Once stamped by success, they are immediately attacked by those who would like to reap without having sown—by men similar to those who, in the preceding century, were successful in robbing Crompton and Hargreave of their inventions, and in condemning these benefactors of their country to poverty. Fowler's patents, the hardly-earned fruits of indomitable courage and perseverance, are now sought to be set aside by men like those who succeeded in breaking down Arkwright's patent, and who attempted the same enterprise against Watt's patented inventions. Our law books are unfortunately full of the records of such patent trials. These attempts are but too often successful in depriving men of genius of the only properties that they can carry to their graves, namely, ideas and inventions. The following is a short account of the great patent trial that has lately so much engaged the attention of the engineering world:—

The case was tried in the Court of Common Pleas, Guildhall, before Lord Chief Justice Erle, and a special jury. Messrs. James Beadel and Richard Lake, in whom, as trustees, the patents are vested, were the legal plaintiffs, while the Messrs. Howard, the well-known agricultural implement makers, of Bedford, were the defendants. Mr. Bovill, Q.C., Mr. Hindmarch, Q.C., and Mr. Aston were counsel for the plaintiffs; while Sir Fitzroy Kelly, Q.C., Mr. Webster, and Mr. Barrow appeared for the defendants. On Saturday, Feb. 21st, Mr. Aston opened the case, and stated that the action was brought for the infringement of two several patents—the first of which was granted to David Fiskin and Thomas Robert Fiskin, and was dated 19th July, 1855 (No. 1629, price 1s. 5d);[*] and the second was granted to John Fowler, jun., and David Greig, Feb. 28th, 1856 (No. 512, price 9d). Although we believe ourselves to be correct in asserting that the Messrs. Howard have infringed several other patents of Mr. Fowler's, nevertheless, probably to simplify the case for the comprehension of the jury, the action was only brought for infringing the patented design for a balance-plough. The pleas for the defendants were, that they were not guilty, and that the letters patent of the plaintiffs were invalid, owing to a want of sufficiency in the specification. These two pleas somewhat contradict each other. If the defendants did not infringe the patents, it mattered very little whether they were valid or not. The second kind of plea always seemed to us to be of a doubtful description. In our number for Feb. 6th, we showed the influence of the patent law on the life of Watt, the principal inventor of the steam-engine. We there stated that the *formal* objections against Watt's patent, act, and specification, seem to have been much stronger than those which were successively urged against Arkwright's patents. In fact, the specification of 1769 did *not* put the public in possession of the invention. *Nevertheless, the mere fact of attacking the patent, on the score of its being informal, showed great immorality on the part of the pirates; a technical defect in a title-deed does not give an honest right to another's land.* Fortunately for Watt, England, and the world, right at last prevailed, and Watt long afterwards used to call the specifications his old and "*well-tried* friends." The history of the past has been said, with no less poetry than truth, to be the mirror of the future; and we thus find a patent case of the latter half of the 18th, repeating itself in the latter half of the 19th century.

Mr. Bovill, in the course of his very able and lucid speech for the plaintiffs, asserted that, "when the patent of Messrs. Fiskin was taken out, the problem of ploughing by steam was solved, and the first approach was made to the construction of a really useful and serviceable steam-plough." To this we fully agree; and we regard No. 1629, date 1855, as the most momentous patent in the history of ploughing by steam. This patent is a further interesting instance of the oft-recurring fact that the most original inventions are often made by outsiders. Mr. William Fiskin is a Scotch Presbyterian minister; while the two other brothers are, or were, schoolmasters in Scotland. The patent has been amended by a disclaimer striking out that which relates to the endless rope; it specifies the construction and use of the plough and of the anchor.[*] Not merely does it thus embody the principle of the balance-plough, but also what appears to us to be an indispensable principle whenever rope traction is used—that of making the anchor self-acting by means of the rope. The use of direct action tackle is evidently only possible to those in possession of this principle. The Messrs. Howard are no doubt well aware of the importance of this plan, and accordingly endeavoured to prove that Mr. Rogers, of Stockton-on-Tees, had invented this arrangement. Mr. Rogers was employed by the Messrs. Fiskin to make the plough, &c., according to a model furnished by the brothers. This witness asserted that he had first invented the self-acting anchor, and that it was inserted in the complete specifications after the provisional specification of Messrs. Fiskin's patent was filed. The self-acting anchor is certainly not described in the provisional specification—a fact of itself sufficient (as proved by several recent legal decisions) to upset the whole patent. Mr. Bovill further described that part of Messrs. Fiskin's invention relating to their balance-plough. In the specification of July 19th, 1855, this plough is described as follows:—"The ploughs or other implements employed are supported in the extremities of forked levers, which are connected to a slotted lever by a bell crank and connecting rod, by means of which the implements are alternately raised out of or lowered into the land, so that while one set is in action the set on the opposite side of the bell crank is out of work. The power for raising and lowering the ploughs is communicated through an endless screw, which gears into a toothed quadrant, carried upon the axis of the slotted lever." It appears to us very probable that the Fiskins did not at first perceive the full value of the balance principle, but merely looked upon it as somewhat facilitating operations at the headlands. The full advantage to be obtained was realized in the patent for the present balance-plough, taken out by Messrs. Fowler and Greig about seven months later than the date of the Fiskin patent. They describe it as follows:—"Several ploughs or tilling instruments are placed at each end of a frame, in order that when the implements at one end of the frame go out of work, the implements at the other end of the frame may come into action; the frame is mounted on an axle in the huddle, and moves thereon as on a fulcrum. The machine has two or more wheels to run on, and is moved to and fro across the land by means of wire ropes, put into motion by a barrel or barrels caused to rotate by a steam-engine. By this arrangement, when the machine arrives at the end of its course in one direction, in place of having to turn it round, one set of implements descend and come into action, and this is effected by the draft of the wire rope taking place in the opposite direction." The ploughs being thus securely fixed on a see-saw frame, each end balancing the other, the draught had a tendency at the end it is pulling to drive the ploughs into the ground whilst it pulls out those at the other end. Mr. Bovill went on to say that, "What the defendants had done, was to adopt the light iron framing of Mr. Fowler's balance-plough. There was nothing, however, in this; but they had done more. In their arrangement they had put the ploughs at each end, on a separate axis, with separate levers; the set at one end operating to assist those at the other end, in the same manner as Messrs. Fiskin had originally done. So far they had taken Messrs. Fiskin's invention. The ploughs were drawn in the same way, by a rope attached to an anchor and passing round the drum of the engine which supplied the motive power. The two axes were connected together, just as Messrs. Fiskin's were—not, it is true, by the precise means, but by a mechanical equivalent which produced the same result. Messrs. Fiskin had an arrangement in the centre, by means of an eccentric movement, for throwing the preponderance of the leverage upon the ploughs that were to operate on the the ground. The defendants, Messrs. Howard, had also made a connection in the centre by means of two eccentric pulleys, over which a chain and rope passed, which produced the same effects. So that, in fact, it was substantially the same arrangement, and threw the preponderance of leverage on the ploughs that were in the ground exactly the same as Messrs. Fiskin's did. Now, if there were this preponderance, as in Messrs. Fiskin's invention, and as the defendants proposed in the specification of their patent, of course a greater power would have to be exerted to raise the ploughs out of the ground than if the ploughs were on a balance. Messrs. Howard very soon discovered that, and accordingly they adopted a plan to remedy it, which substantially made their plough the same in that respect as Mr. Fowler's. This they did by slightly altering the form of the eccentric pulleys and placing them in a particular position, by which arrangement, whilst professing to have their ploughs at each end of separate levers, they put them precisely on the same balance as Mr. Fowler's. Thus, the defendants first took Messrs. Fiskin's plan, of having two sets of ploughs, each on a separate axis; and, having done that, they next, by the chain or rope connected with the eccentric pulleys, joined them together, and made them like Mr. Fowler's." Mr. Bovill then gave an account of the arrangement entered into by Messrs. Howard with Mr. Fowler, for the use of his balance-plough and other patents; which arrangement, after trying to get the patent from Messrs. Fiskin, he (Mr. Howard) refused to carry out. The learned counsel stated,—That "failing to obtain the patent, he now turned round, and said to Mr. Fowler: 'I will put you to the expense of a trial, and try to upset both your's and Mr. Fiskin's patents.'" Mr. Hindmarch put in the different specifications of the balance-plough patents belonging to the plaintiffs, amongst which was a disclaimer filed by the present plaintiffs on the 20th December, 1862, with regard to Messrs. Fiskin's patent, disclaiming certain portions of the invention described in the specification. These portions of the specification are those relating to the way of transmitting the power to the ploughs.

---

[*] We state the prices of these patents in case any of our readers may wish to have the original specifications; they may be obtained by enclosing the amounts, in stamps, to Mr. B. Woodcroft, patent commissioner, Southampton-buildings, Chancery-lane.

[*] We would advise Mr. Fowler to also disclaim that part of his patent, No. 1635, date 1856, claiming the "giving motion to a plough or other tilling instrument by means of two engines, each on a carriage with a single winding drum, mounted on a vertical axis, such engines traversing on the opposite headlands, and each working so as to draw the plough or other tilling instrument towards itself." He will find the same plan specified in patent No. 11,304, date 1846, by John Tulloh Osborn. A somewhat similar plan is also specified in patent No. 11,077, date 1846. The Marquis of Tweeddale also adopted a similar arrangement.

Mr. Hindmarch then examined Mr. Carpmael, who gave his evidence with great clearness and scientific precision. He stated that Messrs. Fiskin's ploughs counterbalance each other to a great extent. In allusion to the question of infringement, the witness described Messrs. Howard's plough as follows:—In this machine, at the end of a carriage on wheels there is a set of levers, each of which has applied to it, at the end, a set of ploughs. The two sets of levers are connected together, and to a common axis, by means of two pairs of chains which are fixed to eccentric levers, by which the two sets of levers, which formerly without those chains were not in a state of balance, and acting upon each other, are now by that means brought in such connection that the lifting, or rather the depression, of one set of ploughs into the land raises the other set, and the raising is assisted even by the descending ones. Therefore, upon this ploughing machine there are two sets of levers and two sets of ploughs, put into such connection that one assists the others in exchange of position.

On Monday, the 23rd of February, Mr. Carpmael was again examined by Mr. Hindmarch. He stated:—"The improvement upon Messrs. Fiskin's patent effected by Mr. Fowler, consisted in fixing the ploughs rigidly upon a frame instead of having them upon a swivel."

In the course of his evidence he further stated:—"I have compared the action of Mr. Howard's plough with that of Mr. Fowler's, and I find that there is no practical difference. It substantially comprises the essential properties of Fiskin's plough, with the addition of the essential properties of Fowler's."

In the course of a long cross-examination by Sir Fitzroy Kelly, this witness stated that the resemblance in point of principle between the defendants' ploughs and that of Messrs. Fiskin's was in the counterpoise, by which one set of ploughs was brought into the aid of the other in effecting a change of position. Sir Fitzroy Kelly examined Mr. Carpmael as to the resemblance between Messrs. Fiskin's plough and that of Campbell, patented in 1849, and described in Vol. 31, page 616, of the Mechanics' Magazine.

Campbell's plough evidently does not come under the designation of a balance-plough. Being further examined as to the difference between Messrs. Howard's and Fowler's plough, this witness said:—"In Fiskin's machine, when you come to the headland, you were obliged, by manual power, to lift the whole weight of the ploughs out of action to the highest position, or rather to a higher position than is necessary for the ploughs coming into action. Mr. Fowler raises the ploughs by the action of the rope, and brings down the other set upon the land. By continuing the pull they are brought into the land, the other set being lifted by the same action up to the highest position.

The real plaintiff in this action, Mr. John Fowler, jun., of 28, Cornhill, and of Leeds, was then examined by Mr. Aston. He stated that his intention was engaged from 1850 to 1853 on the drainage-plough, and since then, on to the present time, on steam-ploughs. He further stated that he was not aware that anyone had used the principle of counterpoise, as applied to a plough, before this was done by the Messrs. Fiskin. In allusion to his own plough, he stated that:—"The rigid fixing of the plough to the frame, and the dispensing with any intermediate basis by which it is not necessary that the power of the men should be injudiciously interfering with the action of the plough, is new in its application. By that I mean the dispensing with the screw-shaft and sector." He further stated that Messrs. Howard's and Messrs. Fiskin's ploughs resembled one another in the arrangement of two sets of ploughs on two sets of levers; the one set going out of action assisting by a counterpoise to raise the set going into action. The plough of the defendants is balanced in this way; the two chains being taken away, the plough would not balance at all; the two lever frames would be independent of each other in action. The two frames being attached to each other by eccentric levers, they are practically brought to a state of balance. Mr. Fowler further stated that he found in defendants' plough other improvements similar to those patented by himself and Mr. Greig—the fixing of the ploughs to a rigid frame, and the balancing of these ploughs over a central axis. Mr. Fowler stated that it had cost him almost £56,000 to perfect his invention up to the end of January, 1862. Being cross-examined, Mr. Fowler repeated the opinions we have quoted as to the novelty of the two patents in question.

On Tuesday Mr. G. Hinton Bovill was examined, and he stated in the course of his evidence that in the defendants' plough the machine is depressed by hand until it reaches the ground, then the draught-rope moves it into the land, and the end of the operation is the same as that which is accomplished by Fowler's plough by much more simple means. He further stated that the chain in Messrs. Howard's machine is a substitution for the slotted levers in Fiskin's plough.—Sir F. Kelly: The chain makes the frame rigid?—Mr. G. Hinton Bovill: Yes; and so far adopts the improvement of Mr. Fowler. The witness further stated that for all the practical purposes of a steam-plough, the levers are upon one frame, and in that respect there is no real or substantial difference between the plough of the defendant and that of the plaintiffs.

Mr. Allen Ransome, of Ipswich, was then examined, and in the course of his evidence he stated that he had paid £5,000 for a licence to make ploughs upon Mr. Fowler's patents.

Mr. Amos, the consulting engineer to the Royal Agricultural Society, was then questioned by Mr. Hindmarch for the plaintiffs. He stated that he concurred generally with the evidence already given.

Mr. Clayton, of the firm of Shuttleworth and Co., the eminent agricultural implement makers, was then examined by Mr. Bovill. He also stated that his firm had paid £5,000 to Mr. Fowler in pursuance to the agreement to which Messrs. Ransome, and Messrs. Burrell were also parties. It was then intended that Messrs. Howard should have taken part in this agreement; but they drew back at the last moment, and tried to enter into a separate arrangement with the Messrs. Fiskin. In the course of the correspondence that took place with Messrs. Fiskin, the defendants wrote:—"You cannot come upon Mr. Fowler or his licenses without you set aside the second agreement by a rule granted in a court of equity; nor can you deprive Mr. Fowler of his privileges without adopting this course, or the one you suggested of assisting to break down the patent." It is evident that Mr. Fowler was bound to commence these legal proceedings, regarding merely the interest of the firms who had adhered to the original agreement.

Sir F. Kelly, in addressing the jury for the defence, stated that he was not disposed to say that there was any ingenuity in Mr. Fowler's balance-plough. On the contrary, all the valuable points were taken from Messrs. Fiskins! To this we would reply in the well-known words of Milton:—

> "The invention all admired, and each how he
> To be th' inventor miss'd; so easy it seemed
> Once found, which yet unfound, most would have thought
> Impossible."

He further asserted that Mr. William Fiskin was "the true and first inventor," and that he had not given his formal consent when the patent was taken out, and no after consent given by him would be sufficient. "A patent was good or bad the moment it was taken out; and as at the time this patent was taken out William had not given his consent, the patent was invalid." This assertion was, however, completely disproved during the ensuing examination of Mr. William Fiskin, who stated that he merely communicated the idea of driving the plough by means of a fixed engine with an endless band, at a high speed. This witness also stated that he had no idea of having first communicated to his brother the idea of a balance-power, and that all the material parts, including the self-acting anchor, were the invention of his brothers.

Mr. Rogers, engineer and iron-founder of Stockton-on-Tees, deposed that he had invented the application of the segment-rack and endless-screw to the plough. As we mentioned before, he also claimed the invention of the self-moving anchor. He also stated that he had received £60, in 1857, to give up all interest in the patent.

Mr. James Howard, being called, gave *his* account of the agreement transaction. He also stated that in Fowler's plan, the ploughs were raised by the draught alone. In his a man was put on it.

Mr. Newton, examined by Mr. Webster for the defence, stated that in his opinion the draught in defendants' machine did not resemble that of Fowler's.

Mr. M'Connell gave a similar opinion, but on being cross-examined, stated that as the shares in Howard's plough fall in the ground they raise the others.

Mr. Pole, C.E., F.R.S., gave evidence in favour of the defence, but on cross-examination acknowledged that the connecting chain in Howard's plough would cause the counterpoise. This was the whole case for the defence.

In answer to the witness Rogers, Mr. Bovill examined Mr. Thomas Fiskin, who contradicted the assertion that Mr. Rogers had invented the self-acting anchor and the application of the screw and sector.

Mr. John Fowler (not a relation to the

plaintiff) stated that he had first introduced Mr. J. Fiskin to Mr. Rogers, and deposed to a conversation he had held with Mr. Fiskin before this introduction to Mr. Rogers, in the course of which the former described the balance-plough and self-acting anchor.

Sir F. Kelly then summed up for the defence. He mentioned, truly enough, that "the anchor described in the provisional specification was totally different from that described in the final specification." This certainly seems to to be the weakest part in the plaintiffs' case. He admitted that Messrs. Howard had adopted the principle of the counterpoise.

Mr. Bovill's reply was mainly a recapitulation of the previous evidence. In the course of his observations he alluded to the fact that Messrs. Howard, on the 15th of March, 1862, had made an agreement with the Messrs. Fiskin for the use of their patented inventions. These patents, however, having been made over to Mr. Fowler, the agreement was worthless; but the very first clause of that agreement was that Messrs. Fiskin should use their best endeavours to induce Mr. Fowler to grant a license to James Howard for the use of their inventions.

On Thursday morning, Lord Chief Justice Erle proceeded to make his charge to the jury. The learned Judge said that "the essence of Messrs. Fiskins' invention was the principle of counterpoise; the essence of Mr. Fowler's invention was an improved mode of applying that principle of counterpoise." The summing up was very justly in favour of Mr. Fowler. The Judge stated that there was no reason for supposing that in 1856 Mr. Howard had any notion of the improvements which he afterwards adopted. The jury having then retired, after a few moments returned into Court, and pronounced a verdict for the plaintiff on all the issues.

It is said that the Messrs. Howard will have the case tried over again in the Court above, before five of the Judges. They will probably base their appeal on the formal objections to the Fiskin patent, and further, on "the glorious uncertainty of the (patent) law." The defendants' plough is a scarcely colourable imitation, and a direct infringement of Messrs. Fiskin's and Fowler's patents. To this the defendants must plead guilty. The formal objections, however, to Messrs. Fiskin's patent appear to us to be very strong. A great portion of the patent has been already disclaimed, but nevertheless, the anchor is not described in the provisional specification, which latter ought not to differ from the final specification.

There cannot be much doubt as to the side on which right and justice are to be found. Unfortunately, law is not always justice, but rather a rough average struck between impracticable justice, and practical injustice. Mr. John Fowler, by his own ingenuity, capital, and undaunted perseverance, has conduced more than any other man to the present advanced state of the ploughing by steam. He has thus absolutely created the very interests that are now opposing him. It may be said that his own guns and shot are turned against himself, by the pirates who want to capture the ship he has built.

Let us hope that a liberal interpretation of the law will save any of Mr. Fowler's patents from being "broken down."

H.

FOULING OF IRON SHIPS' BOTTOMS.

We have often discussed this question, and must return to it. Like the member for Rochdale, we have no confidence in the Admiralty, which never moves out of the orbit of routine, or abandons its traditions except by compulsion. It never swerves from its accustomed obstructiveness, until it has undergone an incredible amount of badgering. On that principle we will again say a few words on the subject referred to.

The Secretary to the Admiralty has frequently brought the evil complained of under the notice of Parliament, but always, as it appeared to us, in a treacherous spirit, which, whilst it lamented in words the obstacle which the fouling of iron ships' bottoms opposed to the construction of a fleet of iron cruisers, seemed to exult in the chance which raised the obstruction, and turned a deaf ear to every rational suggestion for its removal.

Compositions without end have for years been tried and proposed and again tried, but never with anything like success, or indeed with any uniformity in the results. New compositions are being tried, and the noble Secretary somewhat facetiously informed the House that ships' bottoms were being enamelled.

We consider the success of any kind of preparation, in the form of a paint or unguent, problematical. Its effect can only be temporary. All experience has proved that to be the case. The most successful have to be renewed in a few months, and their action depends on the waters in which the ship lies, and the length of time she is in harbour. In many cases the preparation has corroded the iron plates. Whatever may be its nature, the mechanical or chemical effect of any substance, simple or compound, applied to the surface of the plate with the brush can only be of limited duration. The process of enamelling, by which we understand fixing a metallic or mineral material by the application of fire, and in a state of fusion, on the surface of iron plates, offers the hope of a successful result; and we think scientific experiment in carrying out that idea is taking a direction which may lead to useful discovery.

But other well-known methods of protecting iron ships from fouling exist, and have again and again been proposed to the Admiralty. Several of these have been examined and reported upon, but the issue has invariably been the consecrated formula, "their Lordships are not prepared to make a trial of the plan proposed."

Two or three plans of covering iron ships' bottoms with wood, and coppering them in the way employed for wooden ships, have been submitted to the Board. Amongst these, Mr. Grantham, a gentleman of scientific attainments, and thoroughly practical in his ideas, has repeatedly urged the expediency of giving his system a trial. It has been described and recommended in the Mechanics' Magazine. Models of it were exhibited in the International Exhibition, and no doubt were observed by many of our readers. Those models showed the practicability of the invention. Last session there seemed to be a chance of that or some other plan being put to the test. With much emphasis and the usual parade of the anxiety of Government to do justice to ingenious inventions, Lord Clarence Paget informed Parliament that a committee of scientific and practical men, of whom the member for Birkenhead was stated to be one, was appointed to examine and report upon plans for protecting iron ships from fouling. To give greater weight to this announcement, he mentioned that the only objection to the construction of the smaller classes of vessels employed as cruisers in distant stations, was the very difficulty in question. Hence the importance, he said, of finding a remedy.

Nevertheless, the project dropped still-born. It never to this day has been ascertained whether such a committee was appointed or not, or, if it was, whether it sat or examined any plan or ever reported.

This apathy, this indifference, to great national interests is disgraceful. The experiment to test the efficiency of any one of the plans proposed might be made for a few hundred pounds. The wood for the sheathing and the copper exist in the Government dockyards; the labour would be a small expense; and yet the Admiralty resolutely turns its face away from the very notion of so simple and easy a course.

We will not, however, be deterred from agitating this question, which, we hope, will be taken up earnestly in Parliament. To be consistent, those members who advocate an iron navy, should insist on Government devoting a sufficient sum to experiments on coppering iron ships. This appears to us the most rational mode of overcoming a difficulty, the existence of which is made a pretext for continuing the construction of wooden vessels.

Besides Mr. Grantham's system, there are others for effecting the desired object. Amongst them is one of merit, the invention of Mr. Charles W. Lancaster, on the principle of a coating of bitumen, insulating the copper from the iron. It offers some difficulties of execution, but these might be overcome by experience. The plan deserves a trial.

We have also had communicated to us a plan for affixing wood doubling to iron ships analogous to Mr. Grantham's, but which possesses the merit of being applicable to existing vessels, and could therefore be tried at a small expense. By means of dovetailed iron bars rivetted outside the ship's skin, and fitting into corresponding dovetailed slots in planks of wood, the latter are securely fastened to the bottom, and are ready to receive the copper sheathing. The main objection to any plan of this kind is the danger of a solution of copper, formed by the action of sea-water, saturating the wood and exercising its corrosive action on the iron plates. We think, however, that effect might be obviated by interposing an impervious material between the wood doubling and the iron skin; and we would suggest for that purpose a coating of Portland or other marine cement. Our reason for doing so is, that, about a year ago, when the "Ripon" was dismantled and the state of her hull examined, the brickwork at the bottom of her hold, which served as a foundation to the boilers, being removed, the plates underneath it were found in an extraordinary state of preservation. The iron appeared as sound and strong as when it was rivetted to the ship ten or twelve years before, the marks of the roller being visible upon the plates. An investigation into the cause of this remarkable fact, which was reported to the Admiralty, left no doubt that the cement in which the bricks were bedded was the preservative agent. There is no reason why a coating of cement should not be compressed between the planks of wood forming the doubling and the iron skin. The experiment is worth trying, and the more so because a stout doubling of three or four inch planks would greatly strengthen the iron bottom, and protect it from injury in the event of the vessel striking. This plan would remove the objection said to exist to navigating iron bottoms in shallow waters. The additional displacement resulting from the doubling would more than compensate the weight of the material employed in this system of coppering. The carrying capacity of the vessel would be rather increased than diminished. In recommending the House of Commons to urge upon Ministers experimental trials for the attainment of an object important to the public service, we offer these practical suggestions, in the hope they will have the effect of provoking discussion and inquiry.

IRON OR WOOD?

A STATEMENT has been presented to the Admiralty by Rear-Admiral Robinson, Controller of the Navy, on the relative advantages of iron and wood, and cost of these materials, in the construction of ships for Her Majesty's Navy. The Admiral says:—Taking it for granted that it is essential for this country to possess a number of ships armour-plated, equal to that of any other power, the first consideration must be with regard to such ships as we require, whether they shall be of wood or iron. There are two important points involved in this consideration. 1. The nature of the material. Iron possesses these advantages over wood:—An iron ship can be built of larger dimensions than a wooden ship, with no loss of strength. An iron ship has more rigidity and strength of structure, as a whole, than a wooden ship, though locally weak and liable to be penetrated by blows, which would fall harmlessly on a wooden ship. An iron ship has much greater durability in certain parts of the structure—indeed, in all parts where no wood is in contact with the iron—than a wooden ship; and after a lapse of years the iron frame would have suffered next to nothing as compared with a wooden ship. But against these advantages must be set the serious local weakness of the comparatively thin plates of which the bottom of an iron ship is necessarily composed; the danger, consequently, of getting on rocks in such ships; and the necessity which this weakness entails of constructing double bottoms, thwartship bulkheads, water-tight compartments, sluice-doors, &c., and various other complicated arrangements, which add both to the weight and cost of an iron ship; the rapidity with which the bottom of an iron ship gets foul, and the immense loss of all the ship's qualities that follows from the adhesion of marine zoophytes. No practical remedy has been found for this serious disadvantage; repeated docking and cleaning is the only palliative. Add to this the extreme uncertainty as to the quality of the material used—in fact, the small quantity of real good iron of the best shipbuilding qualities that can be found in the market; the prodigious ravages caused by the splinters of iron when the plates are broken and smashed by shot; and the far greater facility with which iron ships can be pierced below their armour plating by submarine guns than wooden ships. Lastly, as the progress that may be made by artillery and all destructive agents of warfare is quite without a limit, the immense price paid in an iron ship for durability may not be an advantage, as new forms for ships of war may, before long, be absolutely requisite. The iron ship of to-day, for which so large a price has been paid, may not be the weapon we require to-morrow. It may, therefore, be wiser and more economical to supply the wants of the moment by a cheaper and less durable structure, which at least is of the same quality as those with which we may have to contend. The most able designer of war-ships in Europe, whose success has been so remarkable, M. Dupuy de Lolme, is of this opinion, and constructs the ships that are to form the French line-of-battle of wood, in preference to iron. 2. The second point to be considered in this question is,—where and how the ships, whether of wood or iron, shall be constructed. If iron is the material preferred, we have the choice of either incurring a large outlay in our dockyards for the requisite plant, or of building by contract. In one dockyard only (Chatham) we can build in iron without any fresh expense. If, therefore, we take the other alternative, and build by contract, the following serious disadvantages attend upon our doing so. The first practical fact that comes before us is, that in no one instance have the contractors kept to their agreements with the Government, either as to time or cost. There is no prospect that more than one out of the four iron ships last ordered will be delivered till many months after the periods agreed upon. It is not one contractor or one iron shipbuilder, but all, who have failed in their agreements; and this clearly indicates the great uncertainty attending this mode of construction. Two other difficulties present themselves,—1. The general slovenliness of the work performed by iron shipbuilders, rendering the presence of an Admiralty Inspector necessary on the premises wherever the contract ships are building, and leading to many difficulties between the contractors and the Admiralty; and 2. The great temptations that beset the contractors, owing to the cost and difficulty of procuring good iron, to use inferior and cheaper material. Again, after a contract is signed, no alteration or improvement, however great, can be made without submitting to any terms the contractor chooses to enforce. Strikes of workmen, strikes of colliers, disputes in trades, all interfere with the progress of the work, and always to the prejudice of the Government. But, if wood be the material selected, the place of building will be our own dockyard, with all the plant, appliances, and materials already at hand. No more money will be required than what already appears in the Navy Estimates; whereas if the ships are built of iron by contract, the whole of the money required to do so must be voted separately, and in addition to the ordinary Navy Estimates; and the increase of the total charge to the country could only be diminished in a very small degree, if at all, by the discharge of a limited number of workmen from some of the yards, who in such a case are entitled to pensions or gratuities, for it would still be necessary to retain that large portion of workmen who are employed in repairs, fitting and refitting ships, and in building the smaller classes which are essential for the protection of our trade in the distant corners of the globe. In every way, therefore, the system of building by contract armour-plated iron ships would be more expensive than building armour-plated ships of wood in our dockyards. The wooden ship, though in some respects inferior in rigidity to the iron, and not quite so strong as a whole, is yet, if we may believe the detailed accounts we have received of such ships as the "Gloire," "Normandie," "Magenta," and "Solferino," perfectly sufficient for the weight it has to bear. Very bad weather has had no effect upon the "Gloire," a wooden ship plated from stem to stern, and therefore far more heavily loaded and more severely tried than any of our iron armour-plated ships have yet been; none of these ships having armour-plates at their extremities. Great addition to the strength of the wooden structures is given by iron beams, iron decks, filling in between the timbers, diagonal bracing, &c.; and, taking all the circumstances into consideration, it seems decidedly preferable, at the present time, to build these ships in our dockyards of wood rather than in private yards and of iron. As a comparison, the probable cost of the "Hector" and "Valiant," armour-plated ships, has been taken; though, being only partially armour-plated, and the accounts not yet completed, an addition must be made, to compare these with the wooden ships proposed to be built:—Cost of a ship of 4,063 tons, iron and partially armour-plated, if built by contract, £206,000; add (estimate), if wholly plated, £8,000—£214,000. Cost of a wooden ship of 4,200 tons, and of greater strength than those now building, wholly armour-plated, for wages and materials (estimated) £170,000; add, as in the case of private firms, for general charges incidental to the above, 10 per cent., £17,000—cost of the wooden ship built in the dockyard, £187,000. The cost of building the "Royal Oak," as furnished by the accountant of Chatham dockyard, for labour and materials, with 2 per cent. added, is £151,970, including the value of materials already provided before the conversion commenced; adding to this 10 per cent. for general charges, as a private builder would do, the cost of the "Royal Oak" for building amounts to about £168,000, subject to any corrections arising from the auditing the accounts when they are completed. The time required to build the iron ship by contract has been 25 months (in the case of the "Hector"). To build the wooden ship leisurely and to the best advantage would take about as long; but if as much pressed as the contractors have been for the "Hector," and if the workmen were entirely uninterrupted, the period might be shortened to 21 months.

AMERICAN INVENTIONS.

AT a recent meeting of the Franklin Institute, Philadelphia, Mr. Howson exhibited a large number of locks, not, as he said, because there was anything essentially new in most of those exhibited, but in order to show the great number of devices which had been produced in order to make locks that would answer for either right or left-handed doors. Mr. H. also exhibited an improved burner for coal oil lamps, invented by Emil Tritten. The wick tube is so isolated, that although it is firmly attached to the burner, the heat from the flame cannot be conveyed to the reservoir so as to vaporize, and thus waste the oil. An extremely simple and ingenious burner for coal oil lamps, the invention of W. O. B. Merrill, of this city, was also exhibited.

B. F. Joslyn's improved revolving pistol for metallic cartridges was exhibited by Mr. H. The cylinder of the pistol, on withdrawing the centre pin, may be pushed to one side without entirely detaching it from the frame. The advantage of this is that the pistol may be loaded and the spent cases removed without any liability of losing the cylinder by detaching it. The centre pin passes through a key so connected to the front of the frame that it may also be turned to the side, and the pin pushed back through the openings in the cylinder, thereby forcing out the cases of the discharged cartridges.

A belt fastener, invented by Messrs. Leibrich and Uitting, of that city, was exhibited. Two eccentric rollers, the surfaces of which are so formed as to present a series of longitudinal ribs having sharp edges, are connected together at the ends by metal plates, in which the journals of the rollers turn. When the surfaces of the rollers are farthest apart, the ends of the strap or belt may be passed upwards between them. On attempting to withdraw the strap, however, the rollers are turned, and the surfaces brought nearer together, securing between them the ends of the belt, which are prevented from slipping out by the sharp edges, or ribs, on the rollers, which hold the ends together with a grip increasing with the force applied to withdraw the ends of the strap.

A combined rule, square, and level, was exhibited by Mr. Howson. The frame of the rule is of metal filled with vulcanized rubber, which forms in the present instance the body of the instrument, although other substances may be used. By means of a strip of metal, jointed, and contained within the rule, and a spirit-level in a recess in the edge of the same, a number of operations, each heretofore requiring a separate instrument, may be performed.

G. F. Witsel's patent combined washing-machine and clothes-wringer was exhibited. In a triangular reservoir vibrates a similarly-shaped dasher, which is so constructed as to form a receptacle for the clothes, which, as the dasher is vibrated, are cleaned by the water which passes through openings in the sides of the dasher, and through the interstices of the clothes. The journals of two rubber-covered rollers turn in the opposite sides of the reservoir, and are so situated that the clothes may be taken from the dasher, and passed directly between the rollers.

Mr. T. J. Weygandt exhibited a thermo-multiplier, an extremely neat and sensitive instrument, made by himself. The chief merit consists in the compactness, the whole of the essential parts occupying a space but little larger than two cubic inches. Mr. W. stated that a fly on the bars would deflect the needle from three to five degrees.

ZERAH COLBURN'S STEAM PUMPING ENGINES.

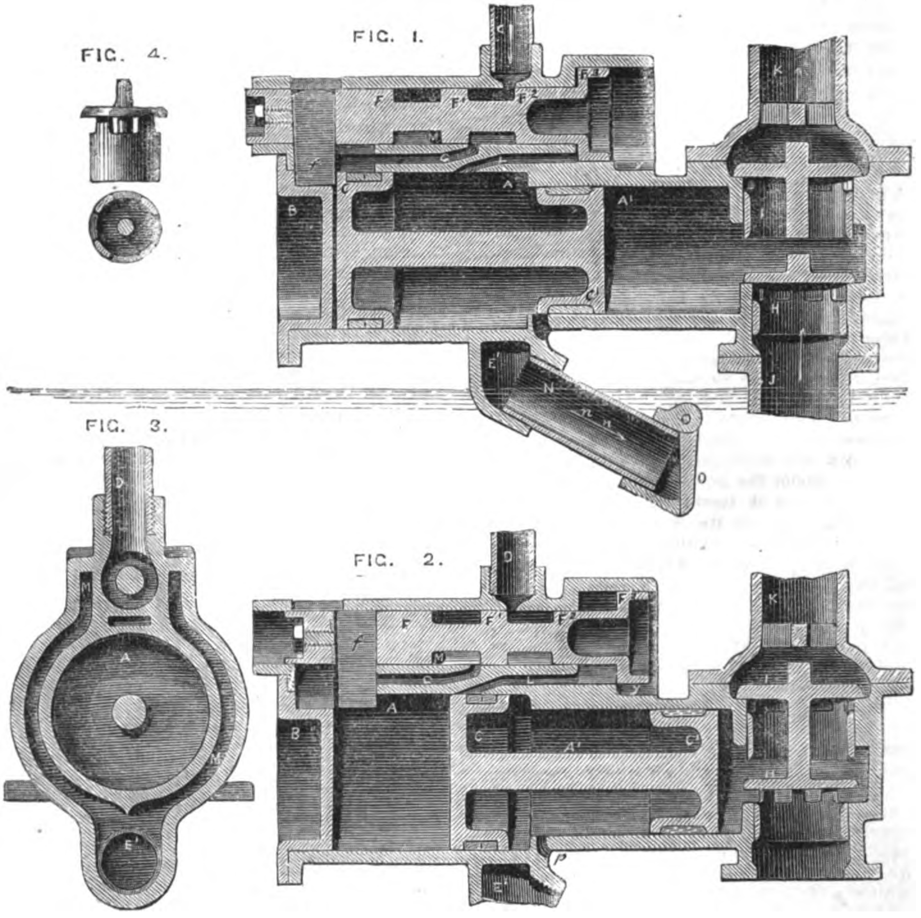

FIG. 1.

FIG. 4.

COLBURN'S STEAM PUMPING ENGINES.

A VERY neat and compact arrangement of steam pumping engine has lately been patented by Mr. Zerah Colburn, of 15, Tavistock-street, Bedford-square.

The steam cylinder and pump barrel are so constructed that they shall form but a single vessel closed at both ends. Within this vessel is placed either a single long piston or two pistons cast, forged, or otherwise firmly joined together, and the distance between the two outer faces of the long piston or of the double piston, as the case may be, is made sufficiently great in proportion to the stroke to prevent the exposure of any single point in the cylinder or pump-barrel to the alternate action of steam and of the water being pumped. Thus for a stroke of 12 in., the total length of the single or double piston is at least 15 in., and, by preference, 20 in. That part of the vessel which serves as the pump-barrel, may be of the same diameter as, or of less or greater diameter than, the part which serves as the steam cylinder, according to the pressure of steam to be used, and according to the height to which the water is to be pumped. When steam is admitted to the steam end of the vessel, the piston is pressed against the water in the opposite or water end, and the piston will make a stroke. Before the stroke is quite completed, the piston is caused to open a valve either directly or through suitable mechanism, and by this valve the steam in the cylinder is discharged into a condenser, so as to leave a vacuum in the cylinder. The pressure of the atmosphere upon the water in the pond, stream, reservoir, or other place from which the water is being pumped will then be exerted, so as to open the lower valve of the pump, and thus cause a pressure upon the water face of the piston so as to force the piston in a direction opposite to that in which it had been previously impelled by the steam. By re-admitting steam and condensing, in the manner hereinbefore described, any number of strokes may be made in succession. In cases where the steam pumping engine is employed in near contiguity to an ordinary condensing steam engine the exhaust steam from the steam pumping engine may be turned into the condenser of the other engine; but where such an opportunity does not occur, the patentee employs in connection with the steam pumping engine a condenser of a kind described in Doctor Ernest Alban's Treatise on the high-pressure engine. The exhaust steam pipe has a flap valve on its outer end, which end is kept constantly immersed in water. One or more small holes are also made in the exhaust steam pipe for the admission of injection water. At every discharge of exhaust steam the exhaust steam pipe is blown through, and the flap valve is opened by the pressure of the steam; but as soon as this pressure falls to that of the atmosphere the flap valve closes, and the injection water coming in through the openings in the pipe condenses the steam and forms a vacuum. The valves of the steam pumping engine, that is to say, those regulating the flow of the steam, are, by preference, of the kind known as piston valves, and are moved by the direct pressure of steam upon them; the steam for this purpose being controlled by a supplementary piston valve worked by the main piston or pistons in the steam and water cylinder. Two of the pumping engines herein described may be made to work alternately, so as to throw a continuous stream.

The obvious effect of these improvements, is to greatly simplify the construction of steam pumping engines, by dispensing with the parts required for or with rotary motion, and dispensing also with counterweights, stuffing boxes, and the more complex combinations of valve gear. It is, indeed, practicable, to construct a complete and useful steam-pumping engine, which, when ready for fixing and for the attachment of the steam and water pipes, shall have but five pieces of metal of any kind, and of which five pieces but two shall have motion.

Compactness is also secured to an extent not before attained, and there is the utmost certainty of action. The pump will work in any position to which the steam valves and water valves may have been made to conform; whereas, Cornish engines, or those in which a weight is attached directly to the pump pole, can only act vertically. This steam pumping engine will work, moreover, without special adjustment to the "lift" at any lift of water for which a corresponding pressure of steam is first provided.

The several figures represent one form of the single-acting steam pumping engine. Fig. 1 is a longitudinal section, showing the steam piston and plunger at the commencement of the steam stroke, or forcing stroke, and the steam valve in position for admitting steam for such stroke. Fig. 2 is a like longitudinal section, differing from fig. 1 only in showing the steam piston and plunger near the end of the steam stroke, or forcing stroke, and the steam valve in position for permitting the steam to be exhausted from the cylinder, and condensed; and fig. 3 is a cross section taken through the steam cylinder in the vertical plane of the inlet steam pipe and exhaust steam belt; and fig. 4 shows the water valves used.

A, A, A, A¹, represent a vessel, of which the portion A, A, forms a steam cylinder and the portion A¹, A¹, forms a water barrel or pump barrel. The portion of this vessel answering the purpose of the steam cylinder being in this case of larger diameter than that serving as the pump barrel, the end of the steam cylinder is left open in casting, and a cover B is fastened by bolts or otherwise, so as to tightly close the end of the cylinder. A double-ended piston C, C¹, one end C of which is intended to receive the pressure of the steam in A, A, and the other end C¹, of which is intended to work against the water in A₁, A¹, is fitted by means of suitable packing, of any well-known kind, so as to be steam and water tight, into the vessel A, A, A¹, A¹. Steam for forcing the piston C, C¹, is admitted in the first instance through the pipe D, and thence passes into so much of the interior space of the hollow cylindrical valve chamber E as is included between the pistons or bosses F¹, F², of the piston valve F, F¹, F², F³. In fig. 2, it will be seen that the part of the piston valve between the bosses F₁ and F² forms a communication between the steam pipe D and the port G, leading to the steam end of the vessel A, A, A¹, A¹, and in this position of the piston valve F, F¹, F², F₃, steam will be admitted upon the steam end C of the double-ended piston C, C¹, which will thus be propelled towards the right hand, and thus make a steam stroke or forcing stroke. At the right-hand end of figs. 2 and 3 respectively are shown the pump valves H and I, and which do not or need not differ in principle from those in general use in force pumps. The water rises through the pipe J, and through the lower valve or suction valve H, and is afterwards forced through the valve I and pipe K to any point to which the pump is made to force.

The water valves H and I are more clearly shown by fig. 3, where it will be more plainly seen that the water passes upward through hollow cylindrical guides formed on the lower sides of the valves, the water escaping, as the valves lift, through apertures cut out of the hollow cylindrical guides, and just below the seats of the valves. It will be seen that the upper valve I is made so much larger than the lower valve H, that when the pipe K is removed and the valve I taken away, the valve H may be lifted out through the seating of the valve I. It will also be seen that the stop to prevent the lower valve H lifting too high is formed as a stalk on the valve I.

With this description of the water valves, we will return to the double-ended piston C, C₁. When this has been forced by the steam to a sufficient distance, the steam end C will uncover an opening or port L, through which steam will then pass from A, A, to press upon the annular face F³ of the piston valve F, F₁, F², F³. By the pressure of the steam thus exerted, this piston valve will be moved into the position shown in fig. 2. In this position the valve F, F^1, F^2, F^3, will have shut off the steam from the pipe D to the port G, and placed that port in communication with the exhaust port M, of which, indeed, there are two, one of which opens from each side of the valve chamber E, extending thence half around the vessel A, A, as shown in fig. 4, and meeting at E^1 at the lower part of A, A. The steam previously admitted to the cylinder will now be exhausted through M, M, and by E^1 into the pipe N. This pipe, although for convenience of drawing it, has not been shown to have a length which would give it a capacity about equal to the steam end A, A, of the vessel A, A, A^1, A^1, should, nevertheless, have a capacity about equal to so much of that vessel as serves the purpose of a steam cylinder. The lower end of the pipe N should be under water, and the lower end of the pipe N should be furthermore fitted with a hinged or flap valve O, or other freely-moving valve permitting the ready escape of the exhaust steam into the water. One or more holes *n*, *n*, are also made in the pipe N at some little distance under the surface of the water, in which its lower end is immersed. Now, when the steam, after doing its work, escapes from the steam end or steam cylinder of the vessel A, A, A^1, A^1, it, the steam, will follow the passages M, M, and enter the pipe N. As the pressure of the steam will at first be considerably greater than that of the atmosphere and of the water acting to close the hinged valve O, that valve will be blown open, the pipe N will be blown through, so as to clear it of any air it may contain, and the greater part of the steam will then be condensed in the water into which it is discharged. At the moment, however, when the pressure of the steam in the pipe N has fallen to the pressure of the atmosphere, the valve O, will be free to close, and as it does so a small quantity of water will enter by the openings *n*, *n*, and thus condense the steam, of a pressure equal to the atmospheric pressure, then remaining in the pipe N. A nearly perfect vacuum will thus be produced in the pipe N, passages M, M, port G, and in the steam end of the vessel A, A, A^1, A^1. The piston C, C^1, having now a vacuum on its steam side, will recede into the vacuous space by virtue of the pressure of the atmosphere, acting in one or both of the following manners:—The pressure of the atmosphere acting on the surface of the water from which the engine is pumping will force up the valve H, as shown in fig. 3, and thus fill the water end or pump barrel of the vessel A, A, A^1, A^1, forcing back the piston or pistons C, C^1, at the same time; or inasmuch as in the case of the particular pumping engine shown, the steam end C of the double-ended piston C, C^1, has a larger area than C^1, and as the air has always free access through the opening *p* to the space between the piston ends C, C^1, the air acting upon the excess of area which C has as compared with C^1, may force the pistons back before the water has time to enter sufficiently to transmit the atmospheric pressure to the surface of C^1. In either case the return stroke of the double-ended piston C, C^1, will have been effected by atmospheric pressure only. The steam previously admitted upon the annular face of the boss F^3 of the piston valve F, F^1, F^2, F^3, will have already escaped through the channel *v*, and therefore when the double-ended piston C, C^1, has returned sufficiently far to strike the arm or cotter *f* projecting from the piston valve, the latter will be moved thereby into its original position, as shown in fig. 2, and in which position another steam stroke will commence. It is to be understood that the arm or cotter *f* is to be so fitted as to allow of no escape of steam.

MERITON'S SPEED REGULATORS.

These improvements in steam engine governors and speed regulators for machinery, recently patented by Mr. T. Meriton, of Hamburg, relate to that description of governor known as the fly wheel governor, the action of which depends upon what may be termed the principle of differential velocities. The improvements consist partly in simplifying this form of governor by dispensing with superfluous parts, thereby effecting economy in first cost, but mainly in rendering more certain, prompt, and efficient its action by improved construction, arrangement, and disposition of parts. A shaft, made wholly or partially hollow, is cut through at portions of its surface so as to form two spiral guides or double-action inclines. Upon this hollow shaft is fitted loosely a fly wheel having at the hub or boss an elongated cylindrical piece or chamber, with guides cut spirally through its surface so as to form double-action inclines. In the interior of the hollow shaft before mentioned is a short spindle or shaft attached to a lever for working the valve. This short spindle or shaft has a pin passing through it in such a manner that the ends project and form as it were two studs, which fit into recesses or holes cut through, or in the inner surface of a ring, which ring has also forged upon its outer surface two studs. The two pin ends or studs within the circle of the ring pass through the spiral guides of the hollow shaft from the short shaft connected with the lever working the valve, and the two studs, without the circle of the ring, pass into the spiral guides in the cylindrical piece or chamber attached to or forming part of the fly wheel.

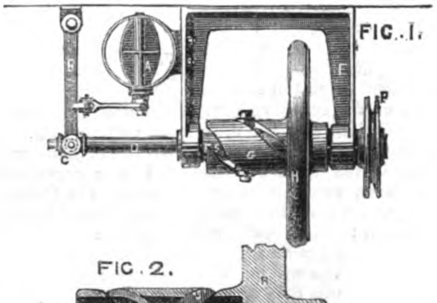

FIG. 1.

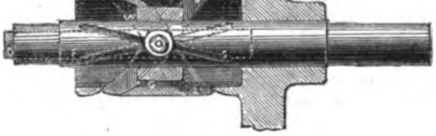
FIG. 2.

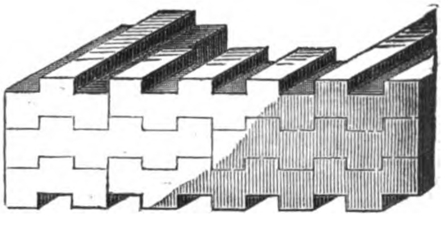


In these engravings the governor is suspended by hangers to a deck beam of the vessel. Fig. 1 is a sectional elevation; fig. 2 is a separate view on an enlarged scale of the hollow shaft and cylindrical piece, for the purpose of showing more clearly the arrangement of spiral guides or double-action inclines. F, F, is the hollow or partially hollow shaft; and S, S are the spiral guides or double-action inclines cut therein; H is the fly wheel with cylindrical piece or chamber G, having also spiral guides or double-action inclines; D is the short spindle or shaft working in interior of hollow shaft, and having a pin passing through its end and through the hollow shaft, and taking into the ring, W, which has two studs, K, K, on its outer surface passing into the guides, in cylindrical piece or chamber attached to or forming part of fly or momentum wheel. These studs may be forged on to the ring, W, so as to form one piece therewith, or they may be screwed; E, E, are the bearers or hangers; A the throttle valve, and B, C, the hinged lever arrangement for communicating the travel of the sliding ring, W, to the valve; P is a pulley for the purpose of driving the shaft, F, by connection with the motive machinery which is to be regulated. This arrangement of regulating apparatus is connected either by pulleys or gearing with the engine, and upon any increase of engine speed, the speed of the hollow shaft, F, will be in excess of that of the fly wheel, H, and the inertia of the wheel, resisting at first the change, will cause the one set of inclines, S, to press upon the studs and draw up the ring, and also the short shaft, D, connected with the valve, A, whereby the valve will be closed. Thereupon the engine speed, and consequently that of the hollow shaft, will fall below that of the fly wheel, H, which will cause the second set of inclines to press upon the studs and return the ring, and also the short shaft to their original positions, thereby reopening the valve without the aid of a spring or a weight, as employed in most governors of this description. It will be seen also that the use of any sliding sleeve is dispensed with. This arrangement, although designed principally for marine engines, is applicable to all kinds of steam and other motive power engines and machinery requiring a controlling or regulating apparatus.

BELL'S PATENT BRICK.

Mr. R. Bell, of Westland-row, Dublin, has obtained a patent for a brick so formed as to bind the work in such manner that it shall form a mass incapable of being riven asunder. These bricks are well adapted for arches, tunnels, and vaults, by forming them of a wedge-like shape, the grooves and tongues corresponding accordingly. The bricks are also suitable for fortifications, embankments, sewers, lighthouses, and for general building purposes.

The bricks are formed with projections or tongues across or along one surface, and with grooves or recesses of corresponding size on the opposite side, whereby they may be laid down one on the other, with the aid of a small quantity of mortar or cement, in such order as to fit or bind together the upper layer with the lower layer, and to tie each other longitudinally and crosswise so as to prevent any lateral or transverse deviation or fissure occurring in the work. The engraving annexed clearly illustrates the shape of the proposed brick.



With regard to bricks for arches a similar system of construction is adopted by means of which it is evident that centres will not be required in the construction of arches and vaults, for as soon as one single layer of bricks has been thrown across the arch the series may be continued by inserting the second layer into the first, into which it will register and be self-supporting, and so on with the entire length of arch, tunnel, or vault. By the adoption of this invention a wall or arch may be constructed with great rapidity and with much greater strength, durability, and saving of expense than by the use of the bricks now in use.

INSTITUTION OF CIVIL ENGINEERS.

March 3, 1863.

C. H. Gregory, Esq., Vice-President,
in the Chair.

The paper read was on "The Perennial and Flood Waters of the Upper Thames," by the Rev. J. C. Clutterbuck, M.A.

The object of this communication was to draw attention to the nature of that portion of the watershed of the Thames comprising the oolitic district, and containing a computed area of 1,500 square miles, situated between the range of chalk hills bounding the vales of Aylesbury and of White Horse, and the Cotswold hills bounding the Vale of Evesham and the Valley of the Severn. It was shown that the Thames ran almost entirely over a clay bed from its source, about four miles west of Cirencester, to its junction with the Thame stream, the limit of the district under consideration; and that it was the mere carrier of waters, whether perennial or flood, brought in by its tributaries, a description of which, in the order they joined the main river, was given. Those running from N. to S. and from N.W. to S.E.—as the Churn, the Coln, the Leach, the Windrush, the Evenlode, and the Cherwell—received their perennial waters from oolitic strata.

Those flowing from S. to N. originated in the chalk hills from the escarpment of which they conveyed the back drainage, slightly augmented by that of the upper greensand, and then passed over the gault and kimmeridge clays, either to the main stream, as the Ray and the Cole, or as the affluents of the Ock and the Thame, from which the principal supply was derived.

The geological condition of the source of the main stream was next noticed; and it was stated that the whole natural bed of the river, from Somerford Keynes to Sandford, below Oxford, was an excavation in the Oxford clay, flanked to the south by the escarpment of the coralline oolite, which rested on a ridge of the clay. As a rule, the lower levels of the valley, including also in many places the oolitic rock, outcropping to the north at a very slight angle beneath the Oxford clay, were covered with drift gravel. Wherever the floods had extended, sand, silt, or argillaceous loam had been deposited on this gravel; and this action was still going on, governed by the number and character of the floods. Thus, the bed of the river was, as a rule, gravel, and the banks a warp, the accumulation of ages. There were instances of the change of bed to the extent of several chains in width; and indeed there appeared to be no limit to these deviations but the physical features of the valley. These facts had an important bearing on any improvement, so much needed, in the drainage or condition of the Thames valley.

The perennial waters are either used for mills, or for navigation. The mills on the tributaries were numerous. Between Thames Head and Cricklade they were, however, virtually deprived of water. From Cricklade to Lechlade the water was not applied to any economical use; and again from Lechlade to Wolvercote, three miles above Oxford, there were no mills. The gaugings of the numerous tributaries, where they joined the main stream, would give the aggregate of the water that it carried; but such observations had been neglected, and as the watersheds were very varied, any estimate of the volume of these streams at different seasons would be difficult. Most of these tributaries were immediately affected by heavy rains, and were subject to flood. The gauging of the main stream was beset with other difficulties; as the height and passage of the water was divided between the mills and the navigation, controlled, indeed, by stringent regulations, but too often disregarded. Though it was not the purpose of this communication to deal with absolute quantities derived from the various sources, yet it was believed the following gaugings, the result of several years' observations by Mr. Stacy, the manager of the mills at Wolvercote, would be received with interest, and would, if carried out in other places, lead to valuable results. There were no mills for thirty miles above Wolvercote, and the navigation, though "flashes" were still sent down, had virtually ceased. Mr. Stacy had found that, in the summer months, the river had a mean velocity of 50 ft. per minute, when the total yield was 8,120 cubic feet per minute, exclusive of the quantity brought down twice a week by "flashes," which it was difficult to estimate. During the winter months, in fine weather, without frost or rain, the river had a mean velocity of 94·9 ft. per minute, and taking the sectional area as 181·5 square feet, this gave a volume of 17,224 cubic feet per minute. In moderate rainy weather, without floods, when the level of the river just reached the high water navigation mark, the total quantity of water passing through the mill was 28,189 cubic feet per minute.

At the end of December, 1862, under similar conditions, the total yield was 35,498 cubic feet per minute, of which 7,738 cubic feet might be taken as the water passing from the main stream to Wytham. These data suggested the necessity of adopting a standard at various stations, so that the results might be compared with the rainfall when the gaugings were taken. At the same time observations were made on the river below the influx of the Cherwell and the Ock, when the yield was found to be 50,995 cubic feet per minute, being an excess of 15,497 cubic feet as compared with Wolvercote, and of which excess it was estimated that 7,689 cubic feet were brought in by the Cherwell, and the remainder by the Ock and the smaller perennial streams. The verification of these quantities was prevented by a fall of rain of nearly half an inch in a few hours, which, at an expiration of 36 hours, doubled the volume of the Thame stream, and added about 30 per cent. to the volume of the main river. At Wolvercote, on the 5th January, 1863, after about one inch of rain, the increase was from 27,986 to 48,418 cubic feet per minute. The rainfall from the 1st to the 7th January, 1863, inclusive, produced a flood in the Thames under circumstances peculiarly favourable for observation. The rain recorded during this period averaged 1·61 in. over the whole water-shed, Dalton's gauge, at Hemel Hempstead, showing a fall of 1·52 in., and a percolation of 1·10 in. The gaugings of the main river at Wolvercote then amounted to 82,500 cubic feet per minute, and at Clifton Hampden, below Abingdon, to 181,832 cubic feet per minute. Of this latter quantity 44,755 cubic feet were delivered by the Cherwell (or an increase of 37,066 cubic feet as due to the flood), 24,864 cubic feet by the Ock, and 29,713 cubic feet by the many smaller streams, water-courses, and land drainage outfalls issuing into the river between Wolvercote and Clifton Hampden, a distance of about twenty miles by the river, with an average fall of 2 ft. per mile, from a computed watershed of eighty square miles. It should be stated that the rainfall on this occasion, on the southern part of the district, was in excess of the average more than half an inch.

The state of navigation between Lechlade and Oxford was then described. It was remarked that from running on one stratum, the Oxford clay, and from other causes, it had ceased to be; although the physical condition of the river bed, and its easy gradients, offered facilities for navigation, for the whole fall in this distance, thirty-one miles, was only 51 ft. 3 in., or about 1 ft. 7½ in. on an average per mile.

The highest recorded floods on the Thames since January 8, 1734, were then alluded to, and details were given of that which occurred March 29-31, 1862. The action of land drainage on flood water was next considered. It was generally admitted that the floods in the main river and its tributaries rose more rapidly than formerly, there being in some localities an advance of 24 in 72 hours within the last 20 years. There was a difference of opinion as to subsidence of the water. As yet, however, it was believed that land drainage had produced little apparent practical effect on the volume of the flood, or perennial waters of the Upper Thames.

There was great scope for improvement in the valleys of the Thames and its tributaries, especially the Thame, the Ock, the Cherwell, and the Evenlode. With a view to prevent injury by floods, Mr. Bryan Wood had successfully carried out several important works, based on a system in which the local drainage was separated from the flood. If by some such plan the floods were brought under control, and the water prevented from remaining stagnant on the land, property would be improved, and the sanitary condition of the Valley of the Upper Thames would be benefited.

ON RADIATION THROUGH THE EARTH'S ATMOSPHERE.*

NOBODY ever obtained the idea of a line from Euclid's definition, that it is length without breadth. The idea is obtained from a real physical line drawn by a pen or pencil, and therefore possessing width; the idea being afterwards brought, by a process of abstraction, more nearly into accordance with the conditions of the definition. So also with regard to physical phenomena; we must help ourselves to a conception of the invisible by means of proper images derived from the visible, afterwards purifying our conceptions to the needful extent. Definiteness of conception, even though at some expense to delicacy, is of the greatest utility in dealing with physical phenomena. Indeed, it may be questioned whether a mind trained in physical research, can at all enjoy peace, without having made clear to itself some possible way of conceiving of those operations which lie beyond the boundaries of sense, and in which sensible phenomena originate.

When we speak of radiation through the atmosphere, we ought to be able to affix definite physical ideas, both to the term atmosphere and the term radiation. It is well known that our atmosphere is mainly composed of the two elements, oxygen and nitrogen. These elementary atoms may be figured as small spheres scattered thickly in the space which immediately surrounds the earth. They constitute about 99½ per cent. of the atmosphere. Mixed with these atoms we have others of a totally different character; we have the molecules, or atomic groups, of carbonic acid, of ammonia, and of aqueous vapour. In these substances diverse atoms have coalesced to form little systems of atoms. The molecule of aqueous vapour, for example, consists of two atoms of hydrogen united to one of oxygen; and they mingle as little triads among the monads of oxygen and nitrogen, which constitute the great mass of the atmosphere.

These atoms ond molecules are separate, but in what sense? They are separate from each other in the sense in which the individual fishes of a shoal are separate. The shoal of fish is embraced by a common medium, which connects the different members of the shoal, and renders intercommunication between them possible. A medium also embraces our atoms; within our atmosphere exists a second, and a finer atmosphere, in which the atoms of oxygen and nitrogen hang like suspended grains. This finer atmosphere unites not only atom with atom, but star with star; and the light of all suns, and of all stars, is, in reality, a kind of music propagated through this instellar air. This image must be seized, and then we have to advance a step. We must not only figure our atoms suspended in this medium, but we must figure them vibrating in it. In this motion of the atoms consists what we call their heat. "What is heat in us," as Locke has perfectly expressed it, "is, in the body heated, nothing but motion." Well, we must figure this motion communicated to the medium in which the atoms swing, and sent in ripples through it with inconceivable velocity to the bounds of space. Motion, in this form, unconnected with ordinary matter, but speeding through the instellar medium, receives the name of radiant heat; and, if competent to excite the nerves of vision, we call it light.

Aqueous vapour was defined to be an invisible gas. Vapour was permitted to issue horizontally, with considerable force, from a tube connected with a small boiler. The track of the cloud of condensed steam was vividly illuminated by the electric light. What was seen, however, was not vapour, but vapour condensed to water. Beyond the visible end of the jet the cloud resolved itself into true vapour. A lamp was placed under the jet at various points; the cloud was cut sharply off at that point, and when the flame was placed near the efflux orifice the cloud entirely disappeared. The heat of the lamp completely prevented precipitation. This same vapour was condensed and congealed on the surface of a vessel containing a freezing mixture, from which it was scraped in quantities sufficient to form a small snowball. The beam of the electric lamp, moreover, was sent through a large receiver placed on an air-pump. A single stroke of the pump caused the precipitation of the aqueous vapour within, which became beautifully illuminated by the beam; while, upon a screen behind, a richly-coloured halo, due to diffraction by the little cloud within the receiver, flashed forth.

The waves of heat speed from our earth through our atmosphere towards space. These waves dash in their passage against the atoms of oxygen and nitrogen, and against the molecules of aqueous vapour. Thinly scattered as these latter are, we might naturally think meanly of them as barriers to the waves of heat. We might imagine that the wide spaces between the vapour molecules would be an open door for the passage of the undulations; and that if those waves were at all intercepted, it would be by the substances which form 99½ per cent. of the whole atmosphere. Three or four years ago, however, it was found by the speaker that this small modicum of aqueous vapour intercepted fifteen times the quantity of heat stopped by the whole of the air in which it was diffused. It was afterwards found that the dry air then experimented with was not perfectly pure, and that the purer the air became the more it approached the character of a vacuum, and the greater, by comparison, became the action of the aqueous vapour. The vapour was found to act with 30, 40, 50, 60, 70 times the energy of the air in which it was diffused; and no doubt was entertained that the aqueous vapour of the air which filled the Royal Institution theatre, during the delivery of the discourse, absorbed 90 or 100 times the quantity of radiant heat which was absorbed by the main body of the air of the room.

---

* Read before the Royal Institution, Jan. 23, 1863, by Professor Tyndall, F.R.S.

Looking at the single atoms, for every 200 of oxygen and nitrogen there is about 1 of aqueous vapour. This 1, then, is 80 times more powerful than the 200; and hence, comparing a single atom of oxygen or nitrogen with a single atom of aqueous vapour, we may infer that the action of the latter is 16,000 that of the former. This was a very astonishing result, and it naturally excited opposition, based on the philosophic reluctance to accept a result so grave in consequences before testing it to the uttermost. From such opposition a discovery, if it be worth the name, emerges with its fibre strengthened; as the human character gathers force from the healthy antagonisms of active life. It was urged, that the result was on the face of it improbable; that there were, moreover, many ways of accounting for it, without ascribing so enormous a comparative action to aqueous vapour. For example, the cylinder which contained the air in which these experiments were made was stopped at its ends by plates of rocksalt, on account of their transparency to radiant heat. Rocksalt is hygroscopic; it attracts the moisture of the atmosphere. Thus, a layer of brine readily forms on the surface of a plate of rocksalt; and it is well known that brine is very impervious to the rays of heat. Illuminating a polished plate of salt by the electric lamp, and casting, by means of a lens, a magnified image of the plate upon a screen, the speaker breathed through a tube for a moment on the salt; brilliant colours of thin plates (soap bubble colours) flashed forth immediately upon the screen—these being caused by the film of moisture which overspread the salt. Such a film, it was contended, is formed when undried air is sent into the cylinder; it was, therefore, the absorption of a layer of brine which was measured, instead of the absorption of aqueous vapour.

This objection was met in two ways. Firstly, by showing that the plates of salt, when subjected to the strictest examination, show no trace of a film of moisture. Secondly, by abolishing the plates of salt altogether, and obtaining the same results in a cylinder open at both ends.

It was next surmised, that the effect was due to the impurity of the London air, and the suspended carbon particles were pointed to as the cause of the opacity to radiant heat. This objection was met by bringing air from Hyde-park, Hampstead-heath, Primrose-hill, Epsom-downs, a field near Newport, in the Isle of Wight, St. Catherine's Down, and the sea-beach near Black Gang Chine. The aqueous vapour of the air from these localities intercepted at least seventy times the amount of radiant heat absorbed by the air in which the vapour was diffused. Experiments made with smoky air proved that the suspended smoke of the atmosphere of West-London, even when an east wind pours over it the smoke of the city, exerts only a fraction of the destructive powers exercised by the transparent and impalpable aqueous vapour diffused in the air.

The cylinder which contained the air through which the calorific rays passed was polished within, and the rays which struck the interior surface were reflected from it to the thermo-electric pile which measured the radiation. The following objection was raised:—You permit moist air to enter your cylinder; a portion of this moisture is condensed as a liquid film upon the interior surface of your tube; its reflective power is thereby diminished; less heat therefore reaches the pile, and you incorrectly ascribe to the absorption of aqueous vapour an effect which is really due to diminished reflection of the interior surface of your cylinder.

But why should the aqueous vapour so condense? The tube within is warmer than the air without, and against its inner surface the rays of heat are impinging. There can be no tendency to condensation under such circumstances. Further, let 5 in. of undried air be sent into the tube—that is, one-sixth of the amount which it can contain. These 5 in. produce their proportionate absorption. The driest day, on the driest portion of the earth's surface, would make no approach to the dryness of our cylinder when it contains only 5 in. of air. Make it 10, 15, 20, 25, 30 in: you obtain an absorption exactly proportional to the quantity of vapour present. It is next to a physical impossibility that this could be the case if the effect were due to condensation. But lest a doubt should linger in the mind, not only were the plates of rocksalt abolished, but the cylinder itself was dispensed with. Humid air was displaced by dry, and dry air by humid in the free atmosphere; the absorption of the aqueous vapour was here manifest, as in all the other cases.

No doubt, therefore, can exist of the extraordinary opacity of this substance to the rays of obscure heat; and particularly such rays as are emitted by the earth after it has been warmed by the sun. It is perfectly certain that more than 10 per cent. of the terrestrial radiation from the soil of England is stopped within 10 ft. of the surface of the soil. This one fact is sufficient to show the immense influence which this newly-discovered property of aqueous vapours must exert on the phenomena of meteorology.

This aqueous vapour is a blanket more necessasy to the vegetable life of England than clothing is to man. Remove, for a single summer night, the aqueous vapour from the air which overspreads this country, and you would assuredly destroy every plant capable of being destroyed by a freezing temperature. The warmth of our fields and gardens would pour itself unrequited into space, and the sun would rise upon an island held fast in the iron grip of frost. The aqueous vapour constitutes a local dam, by which the temperature at the earth's surface is deepened; the dam, however, finally overflows, and we give to space all that we receive from the sun.

The sun raises the vapours of the equatorial ocean; they rise, but for a time a vapour screen spreads above and around them. But the higher they rise, the more they come into the presence of pure space, and when, by their levity, they have penetrated the vapour screen, which lies close to the earth's surface, what must occur?

It has been said that, compared atom for atom, the absorption of an atom of aqueous vapour is 16,000 times that of air. Now, the power to absorb and the power to radiate are perfectly reciprocal and proportional. The atom of aqueous vapour will therefore radiate with 16,000 times the energy of an atom of air. Imagine, then, this powerful radiant in the presence of space, and with no screen above it to check its radiation. Into space it pours its heat, chills itself, condenses, and the tropical torrents are the consequence. The expansion of the air, no doubt, also refrigerates it; but in accounting for those deluges, the chilling of the vapour by its own radiation must play a most important part. The rain quits the ocean as vapour; it returns to it as water. How are the vast stores of heat set free by the change from the vapourous to the liquid condition disposed of? Doubtless in great part they are wasted by radiation into space. Similar remarks apply to the cumuli of our latitudes. The warmed air, charged with vapour, rises in columns, so as to penetrate the vapour screen which hugs the earth; in the presence of space, the head of each pillar wastes its heat by radiation, condenses to a cumulus, which constitutes the visible capital of an invisible column of saturated air.

Numberless other meteorological phenomena receive their solution by reference to the radiant and absorbent properties of aqueous vapour. It is the absence of this screen, and the consequent copious waste of heat, that causes mountains to be so much chilled when the sun is withdrawn. Its absence in central Asia renders the winter there almost unendurable; in Sahara the dryness of the air is sometimes such, that though during the day "the soil is fire and the wind is flame," the chill at night is painful to bear. In Australia, also, the thermometric range is enormous, on account of the absence of this qualifying agent. A clear day, and a dry day, moreover, are very different things. The atmosphere may possess great visual clearness, while it is charged with aqueous vapour, and on such occasions great chilling cannot occur by terrestrial radiation. Sir John Leslie and others have been perplexed by the varying indications of their instruments on days equally bright; but all these anomalies are completely accounted for by reference to this newly-discovered property of transparent aqueous vapour. Its presence would check the earth's loss; its absence, without sensibly altering the transparency of the air, would open wide a door for the escape of the earth's heat into infinitude.

CALIFORNIA MINING IN 1862.

THE *Mercantile Gazette and Prices Current* of San Francisco, publishes an interesting abstract of the progress and condition of mining in California during the past year. It says:—"During the past year the operations in gold mining have usually been attended with fair average success. The gradual diminution of the yield of the older fields has been compensated by the new discoveries that have been made in other vicinities, so that the total gold product of the year has probably fallen but little, if at all, behind that of the past four or five seasons."

Hydraulic Engineering.—California is the most extraordinary country in the world for hydraulic engineering connected with gold mining. Some of the hydraulic works are stupendous in magnitude, and they exhibit great originality of genius, enterprise, and daring. The following extracts from our cotemporary, on this head, are of decided interest:—

"At Michigan Bluff, midway between Downieville and Placerville, on the North Branch of the Middle Fork of the American river, hydraulic mining has been vigorously and successfully prosecuted. Owing to the formation of the land, the sluices are laid in long tunnels, 100 ft. under ground. The water is carried in iron pipes upwards of 3,000 ft., and has a fall of 300 ft. Seven of such tunnels were in use in June, and more than a dozen others were shortly to be commenced to work other claims.

"In Siskiyou, along Scott river and its vicinity, the yield was larger than for several years past, and a number of rich claims were mentioned, in one of which a 450 dol. nugget was found. The river claims were worked very extensively, the number of water wheels erected being greater than ever before.

"At French Carrol, in Pollard's claim, in March last, a tunnel 2,800 ft. long was completed after two years' labour. Seventy-five men were employed and 800 in. of water used in the claim, and 5,000 dols. 17,000 dols. and 20,000 dols. were cleaned up at different times after operations commenced."

Amalgamating.—The only improvement noted during the past year in this class of mining was a greater saving of the gold in the shape of amalgam taken from the riffles and amalgamated coppers of sluices by means of nitric acid. It has been found that what was formerly regarded as refuse and thrown away, if slowly evaporated, frequently still yields a considerable quantity of gold. The Columbia Fluming Company thus save sufficient to pay the salary of their superintendent.

Blasting.—At Smartsville, in Bradley's hydraulic claim, in October, a blast of 500 kegs of powder was fired, for the purpose of pulverizing the hard cemented gravel, and preparing it for washing. The bank was 85 ft. in height. From this a tunnel 190 ft. in length was run, with seven side drifts of 10 to 15 ft. long. In these the powder was deposited, and five lines of fuse carried thence to the entrance. For a distance of 75 ft, from the entrance, the tunnel was then tightly closed, and packed or "tamped" with earth. When the explosion occurred, the hill, for a distance of 300 ft. front and rear, and from the bed rock to the surface—a depth of from 85 to 120 ft., composed principally of hard grey and blue cement—was thoroughly pulverized, and the surface thrown in ridges, as though newly ploughed. The cost of the blast was 3,300 dols. The saving of labour was about 30 per cent. To wash the soil thus prepared would require a stream of 400 in. of water for over three months, for which the outlay would be 5,000 dols, and 1,500 more would be expended for the labour required. 20,000 dols. was refused for the product.

Product of Gold and Quicksilver.— The total value of the treasure obtained from all the California mines in 1862 was 42,539,799 dols., of which 4,989,921 dols. were coined in San Francisco. In 1861 the total value was 41,689,077 dols.: in 1860, 45,211,693 dols. The quicksilver product of California mines is prodigious. Last year it amounted to 3,025,875 lbs.; most of this was exported.

BIDDELL'S RAILWAY CROSSINGS.

THE patentee of the well-known "chilled" cast-iron railway crossings, Mr. G. A. Biddell, of Ipswich, has lately taken out a patent for additional improvements in the construction and manufacture of "chilled" cast-iron railway crossings, for which letters patent were granted, bearing date 19th September, 1855, No. 2113. It has been found that when the chilling of the upper wearing surface of the crossings is carried quite up to the rail ends of the crossing, as in his former patent, the extreme end edges of the chilled wearing surfaces are liable to chip or break off in small fragments from the weight and action of the wheels of the engines and carriages running over such crossings; it has also been found that the "point" in these chilled crossings (where it is formed as a portion of the main casting and chilled upon all its upper wearing surface, thus being made hard and brittle) is sometimes liable to be broken off by a side blow from the wheel flanges, and thus, besides being unsightly, the sharp edges caused by the fracture occasionally cut the wheel tyres running against them. Now the object of these improvements is to remedy the defects and inconvenience above set forth. This is proposed to be done by preventing the chilling action taking place quite up to the extreme ends or point of the upper wearing surface of the crossings. This will leave the parts which have been found liable to chip and break off less brittle, more tough, and much less liable to chip or break than when chilled at those parts as heretofore. This effect is produced by the proper use of "cores," or sand, or other suitable material, in connection with the iron or chill producing portions of the mould previous to casting the crossing.

Fig. 1 is a longitudinal section of a mould in which the patent crossings are cast; and fig. 2 is a plan of a crossing made according to the present invention.

In fig. 1 *a* and *b* are the boxes or flasks which contain the entire mould; *c* is the lower or iron portion of the mould for producing the "chilling action" on the upper or wearing surface of the finished crossing; *d* and *e* are "cores," of sand or other suitable material, for preventing the chilling action taking place at the extreme ends of the wearing surface; and *f* is a similar "core" for forming the point of the crossing. The rest of the mould is formed with ordinary moulding sand, *g*. In fig. 2, *h*, *i*, *j*, are the portions which have been found liable to chip and break off, and are therefore formed by the cores, *d*, *e*, *f*, which prevent the chilling action and leave those parts more tough and less liable to chip or break than when chilled as heretofore.

BIDDELL'S "CHILLED" CROSSINGS.

WEILD'S MACHINE FOR CUTTING AND SHAPING METALS.

MR. WILLIAM WEILD, of Manchester, whose patent spooling machine attracted some attention in the Western Annexe of the International Exhibition, has lately taken out a patent for several improvements in workshop tools.

The following is a description of one of his improvements, consisting in an arrangement of machinery for cutting, shaping, drilling, and rolling combined in one machine. This compound machine is more especially adapted for the manufacture of fire-box stays or bolts for locomotives and other boilers. The action is as follows:—The rod of copper, iron, or other suitable metal to be operated upon is fed forward by the attendant at intervals to be compressed between two dies to form squares, if requisite, at the end of each stay or bolt, while the rod is held between the dies, a cutter descends and cuts off the piece forming the stay or bolt close by the square dies; the piece so cut off drops between three rollers, two of which are in motion, the other roller has a movement given to it in a vertical direction by a cam action from the main shaft; such movement allows the piece forming the stay to get in between the rollers on the top side, and when rolled to drop out from between the rollers on the under side. During the operation of rolling drills are brought into operation for centering the ends.

Fig. 1 is an elevation in section of a machine for shaping, cutting, and rolling copper stays or bolts for locomotive or other boilers, or for shaping, cutting, and rolling other metal, for any purpose to which it may be applicable. Fig. 2 is a front elevation.

a is the framing supporting the driving shaft *b*, to which motion is communicated by steam or other power; the pinion b^1, keyed on the shaft *b*, gears into the wheel c^1 on the top shaft *c*, which is provided with three eccentrics; the eccentric c^1 is for shaping the bar of metal to be operated upon marked *d*, the eccentric c^2 is for cutting off a portion of the bar, and the eccentric c^3, is for actuating the rocking frame *e*, in which the roller *f* revolves. The machinery for shaping the square or other shaped head on the stay or bolt consists of the fixed lower die *g*, and the moveable upper die g^1, screwed to the slide g^2, which is hinged to the link g^3, fitting on the eccentric c^1. The machinery for cutting off the bolt or stay consists of the cutter *h* screwed to the slide h^1, which is connected by the link h^2 to the eccentrics e^2, and the machinery for rolling the stay or bolt consists of the rollers *i* and *j*, which revolve in stationary bearings, and the roller *f* revolving as before stated in the swing frame *e*, which is actuated by the link c^1, and eccentric c^3, the rollers *i* and *j* are made to revolve in the same direction, as indicated by arrows, by the wheel b^2, on the driving shaft *b*, gearing into the wheel *k*, keyed on the cross shaft k_1, on which are fixed the pinions k^2 and k^3; the former drives the roller *i* by

WEILD'S MACHINE FOR CUTTING AND SHAPING METALS.

FIG. 1.

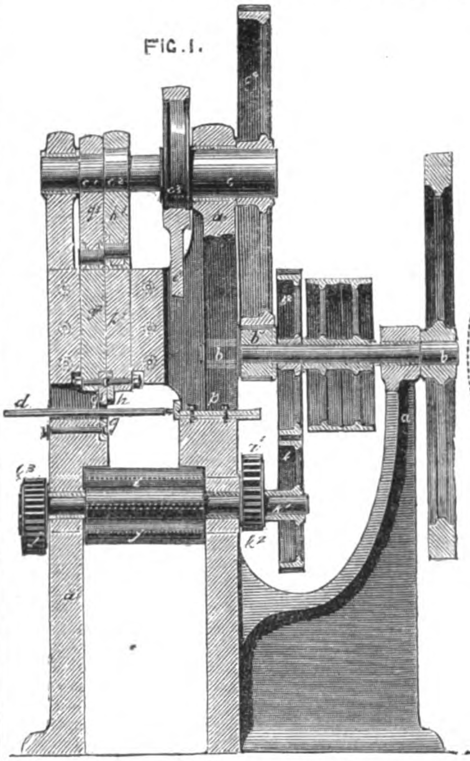

FIG. 2.

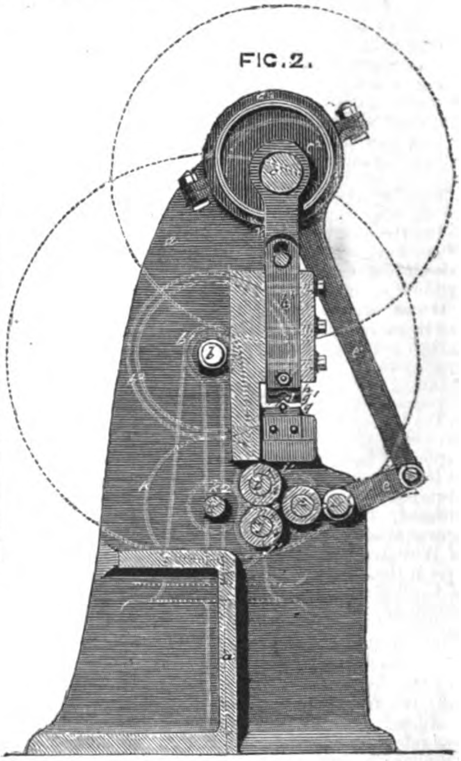


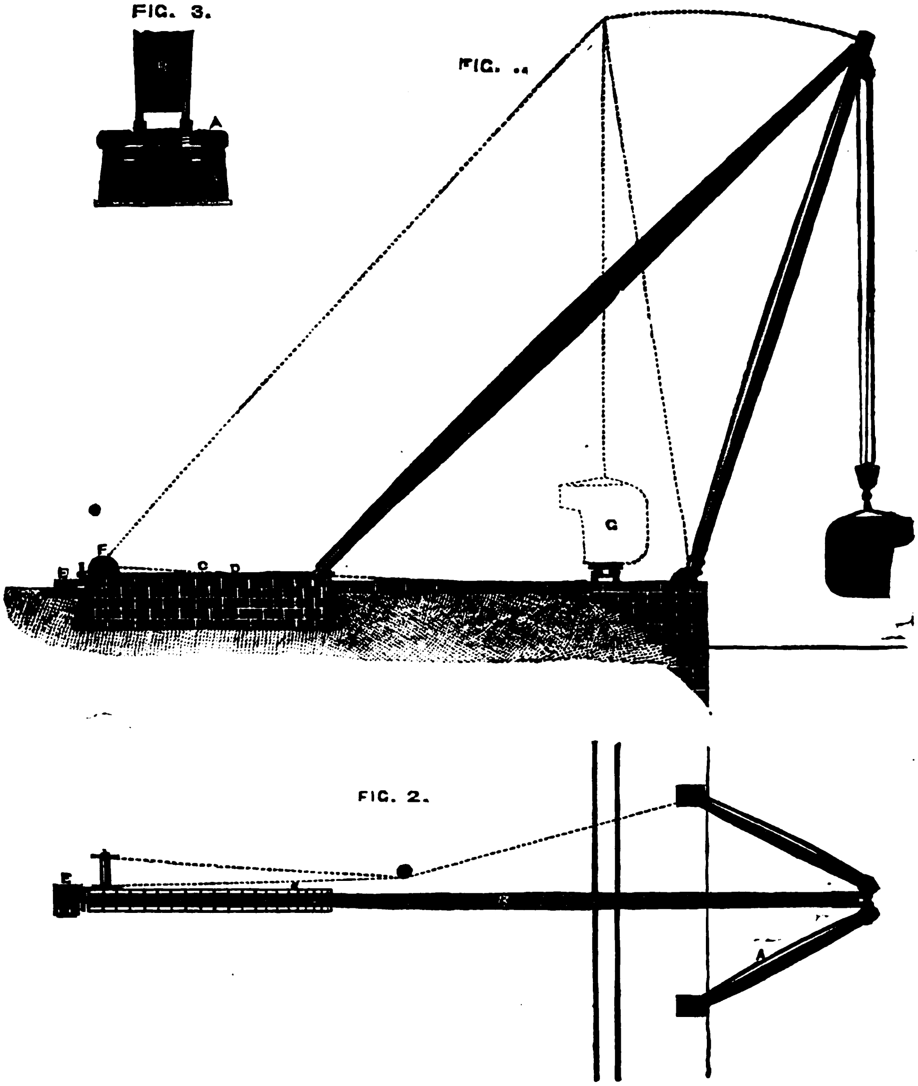
the pinion i^1, and the latter drives the roller *j* by the pinion j_1. The mode of operation is as follows:—The rod of copper, iron, or other suitable metal marked *d* is fed forward by the attendant at intervals, the advance of the rod being arrested by the adjustable stop plate *p* when the rod has been compressed between the dies and g^1, by which square or other shaped heads are formed if requisite at the end of each stay or bolt; while the rod is held between the dies *g* and g_1, the cutter *h* descends and cuts off the piece forming the stay or bolt close by the square dies, the piece so cut off drops between the three rollers *f*, *i*, and *j*; the two latter of which have a rotary motion given to them as above described, and the roller *f* has a movement given to it in a vertical direction by the eccentric c^3; this vertical motion is so timed that when the piece forming the stay or bolt drops, the roller *f* is below the centre of the rollers *i* and *j*, and allows the piece forming the stay or bolt to get in between the rollers from the top side, and the roller *f* in rising compresses and rolls the stay or bolt between the three rollers. When the roller *f* is in its highest position, the rolled stay or bolt drops out from between the rollers and falls into a receptacle placed underneath.

DAY AND SUMMERS' PATENT SHEER LEGS.

ON page 126 of this volume, we noticed a trial of sheer legs at Southampton, the invention of Messrs. Day and Summers, of the Northam Iron Works, in that town. We are now enabled to present our readers with an illustration showing the arrangement. The invention consists, first, in connecting the lower end of the back leg to a screw, worm, pinion and rack, hydraulic ram, or other like mechanical contrivance for imparting to and fro motion to the back leg, in order that it may act as a prop to the front legs when they are moved inwards, and as a guy to them when they overhang outwards. The front legs are of the ordinary construction, and work in the usual manner. The invention also consists in the employment of a load at the lower end of the back leg. This loaded leg then acts to some extent as a back balance.

The engravings show the back sheer leg made to travel to and fro by means of a screw and nut. Fig. 1 is a side elevation of ordinary sheer legs, with the means of working the back leg partly in section; fig. 2 is a plan, and fig. 3 is a cross section in the line *x*, *x*, of fig. 1. A, A, are the front legs, working in the ordinary manner; B is the back sheer leg, connected at top to the front legs in the usual manner; C is a foundation of masonry or other solid work, on which iron plates D, D, are secured; these plates are formed with a groove or channel on their inner sides for receiving trunnions *a*, *a*, which also act as counterbalance weights, projecting from the lower end of the leg B, or from plates connected to it, as shown in the transverse section, fig. 3; *b* is a nut united to the trunnions *a*, *a*, through which a screw *e* passes; this screw is free to revolve in eyes or bearings *c*, *c*, bolted to the foundation; F, F, are wrought-iron plates bolted on to the flanged plates D, D, to prevent the trunnions rising when the leg is made to move to and fro along the channel in the plates D, D. The screw may be worked by a steam-engine, as shown, or it may be made to revolve by hand, or otherwise. F is a chain barrel for raising and lowering weights to be lifted or moved by the sheers.

DAY AND SUMMERS' SHEER LEGS.



THE MANCHESTER ASSOCIATION FOR THE PREVENTION OF STEAM BOILER EXPLOSIONS.

AT the annual meeting of this association, which was held last month, some useful suggestions were made by some of the speakers.

Mr. Hugh Mason said that, in looking at the report, he had noticed with great pleasure the considerable increase made in the number of "Thorough examinations" during the year 1862, as compared with the year 1861, or indeed of any year since the foundation of this association. He had always availed himself of the privilege of having a "Thorough examination" of each of his boilers once a year, having made his arrangements so that this could be done at the ordinary visits of the Inspectors without any extra charge. This being the case, he felt the greatest confidence as to the security of his boilers. He was glad to see that these "Thorough examinations" were increasingly appreciated, since he was convinced that with whatever vigilance "External" inspections were made, still there would frequently be lurking concealed defects seriously affecting the safety of the boilers, which could only be detected on "Thorough examinations." It was only a few days since, that, in consequence of a recommendation received in the report on the Inspector's examination of his boilers, he was induced to drill through some plates that appeared to be thinned by corrosion, and having tested them in that way he felt a confidence in their sufficiency which he could not otherwise have done.*

Mr. Mason then referred to the records kept at the office, which comprised the experience derived from the continued inspection of this association, and thus became a most valuable reference to its members. He then alluded to the subject of incrustation, which the water supplying his boilers was very prone to form. He had consulted Mr. Crace Calvert on the subject, and obtained a recipe, for which he most cheerfully paid him his fee; the advice was simply to put in a certain amount of common soda and logwood sawdust, which he had adopted for the last five years, and found it to prove most beneficial, and therefore recommended the remedy to any one else troubled in the same way.

Mr. Adamson stated that he had supported the association from its commencement, and his knowledge of the advantages which resulted from it would induce him to do so still further. The monthly reports of the engineer demonstrated that the association was of the greatest importance, since they not only gave records of any disasters which had taken place, but also afforded information to one member of any progress attained by another, and thus placed it at the disposal of all. He had taken considerable interest in that most fatal explosion that had lately occurred at Masboro', and had, since its occurrence, visited the works, and examined the fragments of the boiler, as well as read the report of the association's engineer upon it. He found that the results arrived at, in that report, were directly contradictory to those of Mr. Dodd, who was officially engaged by the coroner to investigate the subject, as well as to those of the jury; Mr. Fletcher attributing the explosion to original mal-construction of the boiler, while Mr. Dodd and the jury, to shortness of water. From the examination he had made, he quite concurred with their own engineer, and attributed the explosion to defective construction, and thus did not agree in the condemnation of the poor engine tenter, who, he thought, had been unfairly treated in being committed to prison. He believed that, had the boiler been under the inspection of this association, the flue would not have been allowed to work without a strong remonstrance, the weakness of its construction pointed out, and a suitable remedy proposed. Mr. Adamson next alluded to the subject of "grooving" or "furrowing," already referred to by the President, and stated he was glad that the monthly reports had gone so fully into this subject, and with the views expressed therein he entirely agreed. It was one to which he attached considerable importance; and since there had been several recent explosions of locomotive boilers from this cause, it became a subject in which all were interested, since it affected the safety of every railway traveller. He thought that mechanical action was the most important element in the formation of these grooves, and pointed out that, in the case of the boiler that exploded on the London and North-Western Railway, the furrow had occurred just in the weakest part of the cylindrical portion of the shell, namely, midway between the fire-box and smoke-box, and close to the lap of a single-riveted seam. He thought the only way to prevent this furrowing action, was to make the cylindrical portions of the boiler truly circular. He had also a high opinion of drilling all the rivet holes, which was much superior to punching. Drilling made parallel holes, while punching never could. Mr. Adamson went into this subject with considerable minuteness and detail, and then passed on to the consideration of surface condensation, the adoption of which he thought would be attended with great benefit. He alluded to the fact that the constant use of precisely the same charge of water round and round, had been found to act injuriously upon the surface of the plates, but that by a slight admission of other water, or by permitting the boiler to be coated by a thin film of incrustation, the difficulty was removed. Mr. Adamson then alluded to superheating, stating how important it was to maintain the temperature of the steam while in action, since the total quantity of heat contained in a cylinder full of steam was so small, that it required to be tenderly dealt with and carefully preserved. He considered that very much was due to the president of this association for the experiments he had instituted for the exact determination of various mechanical questions, and that the data which the engineering world was already in possession of through Mr. Fairbairn's exertions had been of great benefit. He remembered the empirical laws which, but a few years since, were laid down by boiler-makers relative to the strength of seams of rivets, the folly of which, he was happy to say, had been rendered manifest by the investigations referred to.

---

* When plates are weakened by corrosion, it is important that they should be tested by drilling through them. An examination merely of the surface is frequently deceptive, especially when the wasting is general and the corroded surface smooth.

Mr. Alexander stated that with regard to the hydraulic test, he highly approved of its application to every description of boiler, whether stationary or locomotive, and had been in the habit for years of applying it himself to locomotives, both old and new; and thought that the frequency with which explosions had lately occurred to this class of boiler, demanded that the objections held by some to this test, should be carefully reconsidered.

SOCIETY OF ARTS.

At the meeting of this society on Wednesday evening, Sir Thomas Phillips, F.S.S., chairman of council, in the chair, the Paper read was "On an International Transit Route through Nicaragua," by Commander Bedford Pim, R.N. The author pointed out the importance of the subject as bearing upon the political and commercial position of this country. He described the railroad that now exists across the Isthmus of Panama, which had now the monopoly of the traffic, the company charging rates of transit that were most exorbitant. As showing the view taken by the American Government of the importance of this means of transit to the United States, the author quoted from the State paper in which the Government aid asked for by the proprietors of the Panama line was granted. This document spoke of the advantages the United States would possess over all competitors for the commerce of the Pacific and the East when the line was completed, which would deprive Europeans of the decided superiority which they formerly possessed in their intercourse with nine-tenths of the world, and would place the States far a-head in the race of commercial supremacy. Captain Pim then described the line which he proposed should be constructed through Nicaragua for the purpose of practically joining the Atlantic and Pacific in European interests. He urged that the monetary interest England has in having at her command a settled and expeditious transit between home and the Pacific, and thence to British Columbia, Japan, Australia, and New Zealand, is very great. This communication should be independent of the control of the United States. His proposed railway starts from Gorgon Bay, on the Atlantic, traverses the intervening land as far as the Lake Nicaragua, then skirting the shores of that lake, crossing the river Tipitapa, and reaching the Pacific at the harbour of Realejo, a total distance of 225 miles. The author stated that the Emperor of the French took very great interest in the subject, and had written a pamphlet upon it himself, in which he especially pointed out the bearing of this question on the commercial interests of England. A discussion ensued, in which several gentlemen took part, amongst whom were Messrs. Charles White (Consul-General for Nicaragua), P. G. C. Curtis, W. Hawes, J. H. Murchison, &c.

GRINDING AND POLISHING TOOLS AND SURFACES.

The use of grinding wheels seems to be extending itself in mechanical workshops. The following is an account of a patent for this description of workshop tool, lately taken out by Mr. George Coles, Gresham-street, City, Mr. J. A. Jaques, and Mr. J. A. Fanshawe, both of Tottenham.

These improvements in the manufacture of grinding and polishing tools and surfaces, relate, in the first place, to a mode of producing such articles by a combination of pulverized gritty or cutting ingredients with a preparation of oxydized or other oil and sulphur, with or without the addition of resinous, gummy, mucilaginous, or albuminous matters.

In carrying out this part of the invention, either emery, pulverized glass, fine granulated iron, or fine iron or steel filings or borings, or other hard cutting substances reduced to a finely divided state, are used, and these substances are combined with any suitable oil and resinous, bituminous, or gummy matter, or mucilaginous or albuminous matters, in some cases with the addition of sulphur or sulphurets, taking care that all the ingredients be well mixed or incorporated, so that the whole mass may be brought as near as possible to a homogeneous state. It is not material to mix the ingredients in very precise proportions, and therefore the gritty or cutting substance, such as the emery, is to be combined in as large a proportion as possible with the agglomerating substance, so that the tool when made may be the more effective. Linseed oil or oxydized oil, with about half its weight or any other convenient proportion of shellac, asphalte, or bitumen added thereto, so as to produce a thick paste, will form a good composition to bind the gritty or cutting materials together, and to this must be added from five to ten per cent. of pulverized sulphur when iron or steel filings form no part of the composition; when those metals are employed as the cutting substance, sulphur must be omitted from the composition. These compounds must then be submitted to about 300 deg. to 350 deg. of heat, in an oven with a dry heat, or in an atmosphere of steam of the requisite temperature, so as to harden the substance sufficiently to admit of it being used as a polishing tool or surface. As the compound before heating will be in a plastic state it may be moulded into any required form according to the purpose for which the tool is to be used. The most generally useful form of grinding tool will be one fixed on an axle, so that rapid rotary motion may be communicated to it. The grinding edge of these tools may be moulded in any shape according to the work they are required to do.

The invention consists, secondly, in combining fine steel or other hard wire with any suitable plastic material, such as that above mentioned, so as to produce a cutting surface like a file or rasp. To this end any convenient quantity of the fine steel or other hard wire is arranged in a suitable manner according to the form of which the tool is to be made, and then the plastic materials are added by forcing them in between the wires, so as to hold or retain the fine steel or other wires in their place. If it be desired to produce a grinding wheel, the wires must, of course, be arranged radially round a centre, and then secured in their proper positions by means of the plastic materials, as before mentioned.

Meetings for the Week.

Mon.—*Inventors' Inst.*, Polytechnic, Renewed discussion upon Capt. Selwyn's paper, "On the Inventions hitherto adopted for the Submergence of Telegraphic Cables," at 8.30 p.m.
Medical, "Clinical Discussion," at 8.30 p.m.
London Inst., "On Music," by Josiah Pittman, Esq., at 7 p.m.

Tues.—*Inst. Civil Engineers*, 1, Discussion upon "The Perennial and Flood Waters of the Upper Thames." 2, "Description of the Lydgate and Buckhorn Weston Railway Tunnels," by J. G. Fraser, Esq., at 8 p.m.
Royal Inst., "On Animal Mechanics," by Prof. Marshall, at 3 p.m.

Wed.—*Soc. of Arts*, "On the Suppression and Extinction of Fires," by C. B. King, Esq., at 8 p.m.

Thur.—*Antiquaries*, Ballot for the Election of Fellows, at 8.30 p.m.
Linnæan, at 8 p.m.
Chemical, at 8 p.m.
Royal Soc., at 8.30 p.m.
Royal Inst., "On Chemical Affinity," by Dr. Frankland, at 3 p.m.
Numismatic, at 7 p.m.
Royal Soc. Club, at 6 p.m.

Fri. — *London Inst.*, "On Economic Botany," by R. Bentley, Esq., at 7 p.m.
Architectural Assoc., "Gothic Woodwork," by R. O. Harris, Esq.
Royal Inst., "On Magnetic Forces," by B. Stewart, Esq., at 8 p.m.
Philological, at 8 p.m.
Royal Horticultural, Council at 11 a.m. Election of Fellows.

Sat. — *Royal Inst.*, "The Science of Language," by Prof. Max Müller, at 3 p.m.

TO CORRESPONDENTS.

The Mechanics' Magazine is sent post-free to subscribers of £1 1s. 8d. yearly, or 10s. 10d. half-yearly, payable in advance. Post orders made payable to Mr. R. A. Brooman, of 166, Fleet-street, E.C.

Advertisements are inserted in the Mechanics' Magazine at the rate of 6d. per line, or 5½d per line for 6 insertions, 5d. per line for 13 insertions, 4½d. for 26 insertions, and 4d. a line for 52 insertions. Each line consists of about 10 words. Woodcuts are charged at the same rate as type. Special arrangements made for large advertisments.

To insure insertion in the following number, advertisements should reach the office not later than 5 o'clock on Thursday evening.

Received.—W. R. M.—L. T.—Captain N.

T. F. S. (Blackburn).—Thanks.

L. M. Not yet received.

W. W. (Portsmouth).—If you like to forward us a plain, clear description, and a similar drawing of your proposed plan, we shall be happy to publish it, supposing that it be really meritorious and novel.

Safety (Newcastle).—There is little doubt, and it is an opinion we have lately expressed in a Paper on "Safety Lamps," that accidents from inflammable gas are often caused by the insufficiency of the light afforded by the ordinary safety lamp. The collier is continually tempted to uncover the light.

Tool-box.—There is no doubt that occasionally reversing the beds of planing machines (when this can be done), equalizes the wear of the slides and keeps them true.

F. A. B. (Llanelly.)—The value of any metalliferous ore can only be ascertained by an accurate quantitative analysis, conducted by a competent chemist.

Boiler Scale.—In addition to Mr. Fletcher, you will find by our number for Jan. 30th, that a member of the Manchester Philosophical Society, Mr. Spence, also advocates the use of *carbonate of soda* in steam-boilers. There is no novelty in the proposal of this chemical nostrum for the purpose indicated. Mr. Spence (whom we believe to be a manufacturer of chemicals) appears to think that the idea is new. The German chemist, Fresenius, in 1851, advocated the use of alkaline solutions, such as carbonate of soda and caustic soda, to render the salts of lime more soluble contained in the water used for raising steam. The idea of using these substances was first originated by the observation that certain waters naturally containing alkaline solutions, deposit no incrustation when used in a steam-boiler. A full account of the rationale of the matter will be found in the "Journal für Practische Chemie," No. 2, 1853. Professor Fresenius persuaded a German manufacturer to adopt his plan. Unfortunately, the plates of the boilers were, shortly afterwards, found to be strongly corroded by the soda. This deleterious action on the plates has been ascribed to the presence of cyanide of sodium in the soda, a substance which is almost always present in the soda of commerce. Another very strong objection would probably be found in the use of an alkaline solution in a steam-boiler. In case the boiler primed at all, the alkaline water would be taken with the steam into the steam-pipes and engines, and thus react upon the joints, packings, &c. The use of almost any chemical in a boiler would always be a delicate matter. The water used would require to be quantitatively analyzed in order to determine the proper amount of the chemical to be added. The firemen would have to be strictly watched to see that the determinate quantity is never exceeded. The efficacy of the given chemical would, evidently, vary in degree for different waters. It may be generally stated that the proposals for using these chemical nostrums almost always take their rise with manufacturers of chemicals; looking for a profitable *debouche* for the waste refuse of their works.

Correspondence.

IRON OR WOOD FOR THE NAVY?

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

Sir,—Was I not right in predicting that the Controller of the Navy would make a bold stand for wood? He has fairly joined issue in the case of "Iron *v.* Wood." He has drawn his brief and pleaded his cause in a statement,* presented to the Admiralty, "on the relative advantages of iron and wood, and cost of those materials in the construction of ships for Her Majesty's Navy." He has put us in possession of the whole of his case—he has set forth his best points and arguments. We can meet him face to face and go fully into the merits of the question.

Admiral Robinson divides his subject into two parts: 1st—The nature of the material (iron or wood); 2nd—Where and how the ships, whether of wood or iron, shall be constructed. On the first point, the Controller honestly confesses that the advantages preponderate greatly in favour of iron. Nevertheless, he comes to the conclusion that wood is the more suitable material. "An iron ship," he says, "can be built of larger dimensions than a wooden ship, *with no loss of strength.* An iron ship has more rigidity and strength of structure as a whole, than a wooden ship, though locally weak, and liable to be penetrated by blows which would fall harmlessly on a wooden ship. An iron ship has much greater durability than a wooden ship, and after a lapse of years the iron frame would have suffered *next to nothing* as compared with a wooden ship. But against these advantages must be set the serious local weakness of the comparatively thin plates of which the bottom of an iron ship is necessarily composed, and the rapidity with which the bottom of an iron ship gets foul."

These two objections, in the opinion of the Controller, decide the question against iron. They outweigh the substantial advantages of strength and rigidity of structure, of durability and peculiar adaptability of the material for ships of large dimensions.

The coincidence between these conclusions, and the arguments advanced by Mr. Reed in support of his system of "wooden bottoms," is so close and so exact, that it goes far to prove the complicity between him and the Controller, which I some time ago alleged was the bond of union between them, and which accounts for the appointment of the former to the office of Chief Constructor.

It will not, I think, be difficult to show that the case got up by the joint efforts of the Controller and his new subordinate, is of the weakest. The main pleas of the advocates of iron are admitted—they are undenied, because they are undeniable; but all-important as they are, they are to be ignored and abandoned, because ships' bottoms made of *thin* iron plates are locally weak, and because iron bottoms foul. We have a case presented to us, in which the points, major and minor, are carefully and correctly set forth—the major are rejected, and the minor are adopted. In iron, we may have ships vastly superior in strength, rigidity, and durability to any ships of wood, and we are to renounce those positive and permanent advantages on account of two objections which may be remedied if not removed. An absolute gain is to be sacrificed to avoid an occasional inconvenience.

But let us see what those objections amount to. On several occasions I have stated my belief that the Admiralty in its ardent attachment to wood, and bitter enmity to iron, knowing the inutility of denying the palpable advantages of iron, eagerly laid hold of the defective points in that material, and pertinaciously thrust them forward, with a predetermination to have recourse to no means, to listen to no recommendations, to make no experiments with the view of ascertaining whether these objections could be removed.

This charge, monstrous as it appears, as against a great public department, is justified by the course taken by Admiral Robinson in his statement. He does not stop to inquire what, or if any, remedies can be found for the minor drawbacks to the use of iron; he says nothing about the proposals which have been urged on the notice of the Admiralty for their removal.

The fact, however, is that many practical plans have been again and again laid before the Admiralty for strengthening the bottoms of iron ships, so as to make them stronger than the bottoms of wooden ships, and for coppering the bottoms of iron ships as effectually as those of wooden ships. But a deaf ear has been turned to every proposition of that kind. The plans are laid aside, no attempt having been made to give them a trial at the expense of a few hundred pounds. For the favourite material, wood, of which the heavy Government purchases are a mine of wealth to the fortunate contractors, millions are lavishly expended; and every kind of experiment, although it be at the expense of an "Enterprise" or a "Favourite," which gives wood a chance, is not considered too costly.

Now that Mr. Cobden's intended motion with reference to "obsolete men-of-war" has brought the question of "iron *versus* wood" so prominently forward, I hope the House of Commons will seize hold of the two points on which the whole matter hinges, and will imperatively call Ministers to account for not having recourse to the most energetic measures, and for not making experiments for the purpose of remedying the only two objections which exist for wholly relinquishing the construction of wooden ships, and for constructing the "Navy" of the future entirely of that material—iron—which undeniably and with the assent of the Controller of the Navy possesesses advantages so vastly superior to its competitor—wood.

I cannot dismiss the first point without reverting to the adroit manner in which the high authority of M. Dupuy de l'Orme's name is cited in support of the construction of line-of-battle ships in wood. Admiral Robinson says that "That eminent designer is of opinion that it is wiser and more economical to *supply the wants of the moment* by a cheaper and less durable structure; and therefore constructs the ships that are to form the French line of battle of wood *in preference* to iron" This is begging the question, and says nothing in favour of wood. The French don't build *iron* line-of-battle ships, because they can't. They employ wood, not *in preference to iron*, but because they are compelled. To produce the iron fleet we have created, and shall have afloat within a period altogether of 3 or 4 years would require 10 years in France; and within another period of 3 or 4 years, we can increase the iron ships in our navy to a number which will make it effective, and which it would take the French another 10 years to equal.

The argument drawn from M. Dupuy de l'Orme's practice falls to the ground. Properly considered, his experience is a condemnation of wood, which, according to Admiral Robinson's own statement, has been used as the material for French iron-clads, not from choice, but from necessity. The leaky condition of the "La Glorie" and "Normandie" has been repeatedly stated in French Naval reports, and, no doubt, is well known to our Admiralty. That we are not in the same predicament as the French from poverty of resourses to build iron ships, is proved by what we have done. It is a lame and impotent conclusion to argue, from the necessity of another nation which does not exist with us, that we must imitate what they are obliged to do when a similar obligation is not imposed upon ourselves. The Controllor and Chief Constructor must be hard driven to make out their case, when they have recourse to so weak and illogical an argument.

The second point, "when and how the ships shall be constructed," is one which requires deep and mature consideration. The best solution of this question will, I believe, be found in a combination of the resources of public dockyards and private contractors, creating a competition between the two in economy and perfection of work, and placing Government in the position of knowing practically what a ship costs and how it ought to be constructed.

Civilian.

WOOD *versus* IRON BACKING FOR SHIPS.

Sir,—Almost the only practical information which the public has been afforded concerning the construction of, and experiments on, the new armour-clad ships, has come to them through the medium of your columns. The able letters of your correspondent "Civilian" have, above all, illuminated the subject; both from the clearness and force of their arguments, and the information as to facts with which they abound.

The advantages which would be possessed by ships constructed solely of iron, as advocated by "Civilian," over combined structures of wood and iron, are no doubt very great—a fact to which the eyes of the Government Committee have evidently been wide open, and to the realization of which their efforts have apparently been mainly directed. It is, however, a question open to serious doubt, whether a wood backing can ever be dispensed with, at all events, until some entirely radical change in the system of construction is adopted, or until the limits at present imposed on the thickness of armour plates by the necessities of manufacture and of naval architecture shall be very greatly extended. A consideration of the effect of shot-impact on an armour plate will at all events indicate the reasons for such an opinion.

When a plate is struck by a shot, the effect on it is twofold, consisting of a movement of the general mass of the plate inwards, with a velocity due to the absorbed momentum of the shot, and also a bulging of the plate on its inner surface, behind the locus of the impact. If there be a wood backing, the plate will be supported over its entire surface, and the motion given to it by the shot will be suppressed by a pressure exerted over a very considerable space, and there will be less tendency to buckle than if the plate were supported by rigid ribs at some distance apart. But the more important considerations in favour of wood backing is due to the effect mentioned secondly, namely, the bulging of the back of the plate. If there be nothing intervening between the skin and the armour plate, it is evident that this protuberance on the plate will cause the surfaces of the skin and plate to be separated, shearing the bolts and tending to rend the skin itself. If the shot strike the plate over a rib, the space necessary for this bulge will be afforded, partly by indentation of the rib, and partly by separation of the plate from the rib. In either case, whether the shot strike over or between the ribs, separation of the plate, skin, and ribs must ensue, causing destruction of bolts and general loosening of the whole structure, while the ribs will themselves be liable to serious injury. The main advantage of wood backing is that these serious, and perhaps absolutely fatal, results are avoided. The space necessary for the bulge is afforded by the yielding nature of the wood with but slight comparative injury to the structure. The assistance which the wood affords the iron in simply resisting penetration, is probably hardly sensible. That is not the object of this backing; and, if it were merely intended for this end, it would not answer the purpose so efficiently as an equal weight of iron added in increased thickness of the plate; but an extra thickness of iron, though it would increase the actual resistance of the plate at its surface to penetration, would not fulfil the vitally important duties performed by the wood backing, namely, the diminution of buckling, of tendency to separation of the layers composing the ship's side, and of liability of the ribs to injury. Besides this, by giving the force which brings the plate to rest, after being set in motion by impact, a considerable distance to act through (owing to the elastic compressibiliy of wood), the backing much reduces the destructive effect on the ship's side.

---

* The statement will be found in page 195.

It is urged that by retaining wood as a material in ship construction, we retain all the disadvantages of combustibility possessed by the former wooden ships. To this, it may be answered, that the great fault of the late construction was not its liability to fire, but its weakness of side, which allowed the penetration of the modern improved shells. The effect of these between decks is, of course, very great, from the smoke, confusion, and devastation they produce; but naval officers, who have, in the late wars, been close witnesses of their effect on ships, do not seem invariably to share the wholesome dread of them which has of late been so frequently expressed by advocates of naval reform in the House of Commons.

If wood is an indispensable element in armour ship construction, it by no means follows that the present mode of applying it is the best possible. In fact, the wood would, perhaps, be best applied merely as a pad between the plates and the ribs, the weight of wood which now backs the plates between the ribs being replaced by a similar weight of iron added to the thickness of the plates. If a plate could be used so thick that it would not be materially bulged by shot-impact, the wood might be dispensed with; but, until some other way is contrived of preventing the "bulge" from doing injury to the ribs, and causing separation from the frame of the ship of the armour plates, wood, or some similar substance, must be employed for this purpose.

The method of attaching the armour plates is at present very imperfect, both from the small amount of retaining force obtained, and from the weakening of the plates caused by the bolt holes. It is odd that the system of attachment round the plate edges has not been more thoroughly tried. It allows the application of almost boundless strength without in the least weakening the plate, and the force is also applied in the most advantageous way to resist "buckling," acting at the extremity of the lever formed by the plate. The experiment made on this method of attachment at Shoeburyness, last summer (*vide* Mechanics' Magazine), was made with a very inferior modification of the original proposal, patented in the beginning of 1862, by Mr. Plum.

It is to be regretted that more publicity is not given to the doings of the Committee on Iron Plates. In most other countries, important researches of this kind would be published as widely as possible, a course which is allowed to be attended with the best results. In the absence of information "by authority," the public is restricted to the information gleaned for them, with difficulty, by the press. If tolerably detailed descriptions and sketches of the various natures of armour structure lately experimented on were to be given in the Mechanics' Magazine, its readers would, no doubt, be greatly interested and instructed.

I am, &c.,
Iron.

AN ATLANTIC TELEGRAPH.

Sir,—Attempts by private enterprise have been lately, and are, perhaps, still, making to obtain funds to go on with the line from Ireland to Newfoundland. Whatever route may be best—on which subject I may, with your permission, make some remarks hereafter—there is, it is fully believed, no chance, as regards any route, of such attempts being successful. It is too much to expect that a *few* individuals should advance and peril their money on such an object. Why concentrate the risk on a few?—thus unwisely intensifying its effects. Why not diffuse the risk over as many as possible?—thus diminishing the risk in the like proportion. As the undertaking, if successful, would confer a vast national benefit, it ought, on every ground, to be made a national matter. We expend millions on Armstrong guns, with a readiness amounting to infatuation; but were Mr. Gladstone asked for a tenth part of the sum so expended to construct a telegraph to North America, we should be treated with fine, round, polished platitudes about private enterprise. Now, which would be most actively promotive of civilization, Armstrong guns, or a working telegraph to America?—which would be most creditable to the 19th century? There is no objection to the gun and also the iron-clad ship hobbies being ridden to a fair and due extent; but they need not be ridden so very hard, so very expensively, so very exclusively. Government is bound not merely to provide the means of protecting civilization, it is also equally bound to use every means for actively promoting it. By diligent attention to the latter duty, the discharge of the former will be rendered more and more easy, and more and more inexpensive.

A working telegraph to America, constructed by the Government of Great Britain, would be a most memorable—a most civilizing event—one to be looked to ever after with pride. By being national, the nation would be entitled to the whole honour—there would be nothing about it of the selfish, narrow, private exclusiveism of private companies. And suppose it cost £500,000, that would only be *fourpence* from each of the inhabitants of the United Kingdom—that would be the measure of their risk. And whatever may have been the case in times past, Government business in the present day is just as well, as effectually, and as economically conducted as any private business whatever. Each has its own sphere, and the construction of the *first* telegraph to America, falls within that of Government. We can have as many after, by private enterprise, as private individuals please. Will our Government perceive their duty? Or will they allow themselves to be blindly guided by a principle good enough in the general case, but most detrimental in its operation here. All the chances are that their efforts would be crowned with complete success. But, even were they not, the nation in such matters is always disposed to be very indulgent—and rightly so. But if the matter were rightly gone about, there can be no doubt of entire success. H. K.

Edinburgh, March 9, 1863.

THE STRENGTH OF IRON.

Sir,—In Mr. Colburn's excellent paper upon iron, read before the Society of Engineers, he mentions the fact that five tons per square inch section, whether in extension or compression, is the maximum strain allowed by the Board of Trade for wrought-iron structures. Now this appears to be a great inconsistency, for it is no more or less than a premium for the use of bad iron; whereas, if no limit of strain per inch were specified, but instead, that the maximum load should never exceed a certain proportion of the breaking weight of the iron used in each particular structure (whether 1-3rd 1-4th or as might be determined), then the engineer would have an important interest in procuring first-rate material, for the purpose of saving weight, and a healthy competition for *quality* among manufacturers would be the result. But as anything will comply with the present requirements, price no doubt as a rule governs the quality. Had no such restriction as to strain existed, the discussion as to the safety of Chelsea-bridge chains would never have occurred, as their strength—whether as regards the point at which elasticity begins to be permanently damaged, about 14 tons per square inch, or the breaking strain, about 26 to 28 tons per square inch—will contrast most favourably as compared to many structures about which no question has been raised. H. H. K.

THE PERSIAN GULF CABLE.

Sir,—As the Persian Gulf cable is now under contract, we may expect that before the close of this year England will be in telegraphic communication with India, the Indian system being completed to Rangoon; and as I observe an influential deputation has had an interview with the Chancellor of the Exchequer to ask the Government for assistance in laying a line from Rangoon to Singapore, Java, and China, it may not, perhaps, be premature to consider the route which should be taken in order to connect the Australian colonies with the Anglo-Indian line.

Several schemes have been made public, but Mr. Gisborne's proposal for a cable round the coast, from East Java to Moreton Bay, a distance of 3,021 knots, has been more fully discussed, and has the merit of being more feasible, to a certain extent, than either of the other submarine lines projected.

Now, as Mr. M'Donald Stuart has again successfully crossed the Australian continent (as is well known), reaching the Indian Ocean, and planting a flag a little to the eastward of Cape Hotham, returning by the same route without difficulty, and reporting as favourably as ever of the major part of the country, which he has now traversed three years consecutively, I think it is worthy of consideration whether a direct overland line would not be practicable, commencing at a point on the north coast, nearest the Island of Timor, and passing through Central Australia, thus connecting the sea line with the various systems now in operation.

Mr. Stuart reports that the country is being speedily occupied, and it is stated that stations could be placed within comparatively short and workable distances, in a good pastoral country, with cattle run attached, which would induce persons of the required intelligence to accept the charge, at a moderate remuneration, of keeping the line in working order.

The length of this land section might be some 1,400 to 1,500 miles; the sea line from East Java, *via* Coepang, to the point on the north coast alluded to, about 940—giving a total of about 2,400 miles.

This is the shortest and most direct route that has been proposed, and as the geographical knowledge, which has resulted from Mr. Stuart's exploration, tends to prove the practicability of carrying out the line indicated, I hope it will receive that attention which it appears to be entitled to, when Mr. Stuart's journal comes on for reading at the Royal Geographical Society, which, I observe, is fixed for the 9th inst.

I am, &c.,
March 3, 1863. W. B. Passmore.

THE DENSITY AND RIGIDITY OF THE EARTH.

Sir,—With reference to the communication of Professor Thomson to the Royal Society, the abstract of which is to be found in your number for Feb. 13th, I should be glad if you would make room for the following quotations, which prove that the increasing rigidity of the earth's materials with their distance from its surface, is a fact not by him for the first time set forth.

In a letter of mine to one of your contemporaries, I have observed:—"As the density of the earth increases towards its centre, it must follow that, taken as a whole, the density of any part is greater than that of anything on its circumference. . . . As a proof of its increasing density, there is the fact of its supporting itself, and preserving its shape, which it would not do were its density uniform. A body of uniform density can only support itself within certain limits, thus:—A piece of timber cannot (could not) support itself when produced, *ad. lib.*, both ways. A dew-drop supports its shape and preserves its globularity; but when two or more unite, we have a compressed shape." It is true that the term "rigidity" is not here made use of; but, inasmuch as Professor Thomson apparently considers it to be the result of the enormous pressure, or, which is the same thing, and follows from it, the increasing density of the earth's materials, and not an original greater force of cohesion, which is my case, our views are one; and the fact that to speak of the greater density of a substance rendered denser by compression, but not otherwise denser, necessitates the idea of its increased rigidity, tenacity, or cohesion, proves that this condition is involved in my explanation, whether or not it was considered to be the cause of the uniformity alluded to, concerning which point I am not certain.

I have not the slightest desire to receive any undue credit for the remarks, and freely confess that my illustrations do not clearly make out a claim to the idea in question. Still, you will, I think, allow that the fact of increasing rigidity, resulting from increasing pressure, was here tacitly assumed.

I am, &c.,
J. Alexander Davies.

March, 1863.

"THE STEAM-ENGINE EXPLAINED BY THE USE OF THE INDICATOR."

An error occurred in the letter of Mr. J. Hopkinson, which appeared in our last number. The price of the volume is 12s. 6d., and not 2s. 6d.

Gossip.

The Duke of Somerset has conferred honour on himself by appointing Commander Robert Scott to the "Fisgard." This is a strong evidence of the disposition of the Lords of the Admiralty to promote deserving men. Commander Scott possesses considerable professional and scientific ability; and during the last two or three years he has done as much, if not more, than any man in England to expose false systems of artillery which have been paraded before the public, to promote scientific discussion, and to further the best interests of the country. He has laboured successfully and disinterestedly through the press and in more than one scientific society; and we are glad to know that his attainments, unflagging industry, and high character have been so far appreciated.

Mr. George Parry, of Monmouthshire, in a letter, says:—A distinguished metallurgist, writing to the *Times* in August last, referring to the manufacture of steel, observes: "The processes now in operation are founded on two opposite principles, namely, putting carbon into wrought iron and taking carbon out of pig iron." The latter has been adopted by Mr. Bessemer, the former by me; but both principles are as old as the hills, the improvements being in the mode of manufacture. On the one principle, cast steel, in large masses, from pig iron direct, are produced; on the other, the same from wrought iron—and from both without the use of crucibles. The one requires the careful selection of pig iron from selected ores; the other embraces all kinds of wrought iron, made from any known iron ores, with but rare exceptions. On Mr. Bessemer's principle, the puddling furnace is entirely dispensed with—in mine, its use forms the whole foundation of success. He makes his steel rails direct from pig iron—I manufacture mine from old, worn-out, wrought-iron rails, &c. The first cast-steel rail (a bridge rail) rolled by my process, was made from an old, worn-out wire rope. How could this be done "upon Mr. Bessemer's principle?" Again, upon his principle, pig iron is converted into cast steel without the use of fuel—in my conversion of wrought iron, fuel is used, both in the solid and the gaseous state.

The following letter on "Iron *versus* Wood" has appeared in the *Daily News*:—

"Sir,—As our mutual object is the good of our country, perhaps you will have the kindness to insert the following remarks upon your able article of this day on wood and iron ships.

"My 'proclivities' have been always for iron, but I cannot get over the following objections to that material for powerful fighting vessels of war. I do not include in this description vessels of the 'Alabama' class, which do not require any shot-proof protection, but great speed to enable them to cut up an enemy's commerce and communications, and great lightness and buoyancy to be good and safe sea boats.

"The first serious objection to iron ships for war purposes is, that the shot-hole made through iron plates is rather larger than the shot itself, while that made through wood is more than half filled up again by the elasticity of the wood fibres returning to their original position, any splinters of consequence being torn off from the inner surface alone. The rush of water would be therefore tenfold greater through the iron shot-hole than through the wooden, whilst the latter are also more easily plugged up.

"The second equally great and heretofore insuperable objection arises from the rapidity with which the iron bottom fouls, particularly in warm climates. Now, as speed is one of the cardinal qualities a man-of-war ought to possess, unless large iron vessels have dock facilities for cleaning the bottoms at least every two or three months, it is clear their usefulness as efficient vessels of war must be reduced almost to nothing.

"The third objection is that many wooden ships that have run aground have been saved by parting with their false keels, and so having water enough to float off. This cannot happen to an iron vessel which has no false keel.

"If, as I firmly believe, artillery of gigantic calibre will be used at sea as well as by land, the the danger of shot holes becomes still more imminent when the ship is iron.

"If we take iron as the ship-building material, under such circumstances, we shall then certainly be obliged to use, as I recommended in the Crimean war, for our gunboats, such a quantity of buoyant materials in the construction of the interior of the ships as will enable them to float even if filled with water.

"In speaking of iron vessels, I do not mean the iron shot-proof vessels, but those built of the usual shipbuilding iron plates; the day of the former is now unequivocally passing away by their being no longer invulnerable. "I am, &c.,

"R. G. Sartorius, Admiral.

"United Service Club, March 11."

The engineer of the Cornwall Railway (R. P. Brereton, Esq., of 18, Duke-street, Westminster) has made a report, in which he says:—The works upon the line from Plymouth to Truro continue in good condition, and the permanent way in good working order. At the Saltash station a goods' shed has been erected and open for traffic. At St. Austell a new road and approach to the goods' shed and mileage siding have been completed; a block of stores and siding in connection with them are in course of construction, and will shortly be ready for occupation. A siding and weighbridge have been completed at Burngullow, as also a passenger platform; and a booking-office is about to be commenced. During the last half-year the works upon the line between Truro and Falmouth have proceeded rapidly, and are fast approaching completion. Many of the cuttings are completed. About 680,000 cube yards of earthwork have been taken to embankment, 280,000 of which have been excavated during the last half-year. A total of 35,000 cube yards of masonry has been executed, 19,000 having been completed in the last six months. All the bridges, 35 in number, are, with the exception of four, either finished or in progress. The masonry piers of all the viaducts but Carnon are completed. At this place some little trouble and delay occurred in getting in the foundations in the bed of the river, but several of the piers are now finished, and all the others are proceeding. The superstructure of all the other viaducts has been erected, with the exception of College Wood, at which place the superstructure is in progress, six of the openings having been completed. At the tunnels of Sparnick and Perran, a total of 394 and 319 lineal yards has been completed, leaving only 90 yards and 43 yards respectively to execute. Upwards of a mile in length of railway has been ballasted ready to receive the permanent way. The rails have been delivered, and the other permanent way materials are in course of preparation. The station buildings and goods' shed at Perran and Penryn are in a forward state.

Soldering.—Soldering is the art of uniting surfaces of metals together by partial fusion, and the insertion of an alloy between the edges, which is called solder, it being more fusible than the metal which it unites. Solders are distinguished as hard and soft, according to their difficulty of fusion. Hard solders usually melt only at a red heat, but soft solders fuse at lower temperatures. In applying solder it is of the utmost importance that the edges to be united should be chemically clean—free from oxide—and they should be protected from the air by some flux. The common fluxes used in soldering are borax, sal ammoniac, and rosin. Hard silver solder is composed of four parts of fine silver and one of copper, made into an alloy and rolled into sheets. It is quite difficult of fusion. Soft silver solder is composed of two parts of silver, one part of brass, and a little arsenic, which is added at the last moment in melting them. It will be understood that these alloys are commonly run into convenient bars or strips for use. Silver solders are used for soldering silver work, gold, steel, and gun-metal. A neater seam is produced with it than with soft solder. It is commonly fused with the blow-pipe. A strip of thin silver solder is laid on the joint to be closed, the blow-pipe is brought to bear upon it, when it melts and runs into the joint, filling it up completely. Button solder is employed to solder white metals, such as mixtures of copper and tin. It is composed of tin ten parts, copper six, brass four. The copper and brass are first melted, then the tin is added. When the whole is melted the mixture is stirred, then poured into cold water and granulated, then dried and pulverised in a mortar for use. This is called granulated solder. If two parts of zinc are added to this alloy, it makes a more fusible solder. Fine gold cut into shreds is employed as a solder for joining the parts of chemical apparatus made of platinum. Copper cut into shreds is used as a solder for iron. Hard silver solders are frequently reduced to powder, and used in that condition. Soft solder consists of two parts of tin and one of lead. An excellent solder is made of equal parts of Banca tin and pure lead; it is used for soldering tin plate, and, if well made, it never fails. The following is a useful table of solders with their fusing points:—

No.	Parts of Tin.	Lead.			Melting deg. F
1	1	25			558
2	1	10			541
3	1	5			511
4	1	3			482
5	1	2			441
6	1	1			370
7	1½	1			334
8	2	1			340
9	3	1			356
10	4	1			365
11	5	1			378
12	6	1			381
13	4	4	1	Bismuth	320
14	3	3	1	,,	310
15	2	2	1	,,	292
16	1	1	1	,,	254
17	1	2	2	,,	236
18	5	3	3	,,	202

The alloy No. 8 is used sometimes for soldering cast iron and steel; the flux used for this purpose is sal ammoniac, but common resin may be employed. Gold and silver are sometimes soldered with pure tin and a flux of resin. Copper, brass, and gun-metal are soldered with No. 8 and a flux of resin or sal ammoniac. The chloride of zinc is used for soldering sheet and plate iron as a flux with the same solder. Lead and tin pipes are soldered by plumbers with Nos. 6, 7, and 8, and a flux of resin and sweet oil. In soldering with soft brass, the ends of the article to be soldered are secured together by a wire, and granulated solder and powdered borax are mixed in a cup with a small quantity of water, and spread along the joint with a spoon. The article is then placed in a clear fire, and the solder melts at a bright red heat, when the article is then removed from the fire. In soldering small articles with the blow-pipe, they are supported on a piece of charcoal, or, what is better, pumice-stone, and the flame is ejected upon the solder. In soldering lead pipes, the parts to which the solder is not to be attached are usually covered with a mixture of lamp-black and size. In soldering any articles care must be exercised to have the edges of the plates or articles perfectly clean, or the solder will not adhere. A flux is employed for the purpose of preventing oxidation. Resin and sal ammoniac, powdered and mixed together, make a good flux for copper and sheet iron soldering. In other cases, a strong solution of sal ammoniac is used to moisten the edges of the joint. Then the resin is sprinkled upon it, and the solder applied. The chloride of zinc is made by dissolving pieces of zinc in muriatic acid. It is well adapted for soldering zinc plates and pipes, and is applied with a brush to moisten the edge of the article to be soldered. The solder is then applied in the usual way with a tool. Zinc is a very difficult metal to solder, because it is so easily coated with oxide, and it also volatilises with heat.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

The Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

Steam Engines, &c.—*none.*
Boilers and Furnaces, 2257.
Roads and Vehicles, including railway plant and carriages, saddlery and harness, &c., 2264, 2278, 2290, 2297.
Ships and Boats, including their fittings, 2274, 2276, 2280, 2287, 2301.
Cultivation of the Soil, including agricultural implements and machines—*none.*
Food and Beverages, including apparatus for preparing food for men and animals, 2294, 2296.
Fibrous Fabrics, including machinery for treating fibres, pulp, paper, &c., 2270, 2291, 2304.
Buildings and Building Materials, 2258, 2261, 2263, 2272.
Lighting, Heating, and Ventilating, 2285, 2300.
Furniture and Apparel, including household utensils, time-keepers, jewellery, musical instruments, &c., 2260, 2271, 2279, 2282, 2284, 2286, 2302, 2305, 2306.
Metals, including apparatus for their manufacture, 2266, 2293, 2303.
Chemistry and Photography, 2265, 2275, 2277.
Electrical Apparatus—*none.*
Warfare, 2281.

Letter-Press Printing—*none.*
Miscellaneous, 2256, 2259, 2262, 2267, 2268, 2269, 2273, 2283, 2288, 2289, 2292, 2295, 2298, 2299.

2256. C. A. Wheeler. *Improvements in machinery for perforating paper.* Dated August 12, 1862.

This invention consists in a hand-power perforator, and relates more particularly to portable or hand perforating machines for the table, shop, warehouse, or counter, as herein described. It is not, however, intended to restrict the application of the principle to the portable or hand form, as the rotary disc perforator and plain flat-surfaced bed-plate (which constitute two of the main features of the said improvements), as well as the peculiar construction of the gripping and riding frame (which forms a third feature of the invention) can be applied in the formation of similar machines of almost any capacity required, and which larger machines, when fitted with suitable gearing, may be worked by steam or other power. It is also intended to apply the same combined principle of construction as regards the rotating perforator or cutter, and gripping and rising guide frame, which answers the double purpose of holding the paper or other material securely in the required position for being perforated or cut, while it also acts as a guide for the rotating perforator for perforating or partially or wholly severing paper, cloth, and other fabrics or materials, whether in single sheets, laminæ, or folds. *Patent completed.*

2257. A. Delrue. *Improvements in compositions for preventing and removing incrustations in boilers.* Dated August 12, 1862.

These compositions are composed entirely of vegetable matters, and are prepared by dissolving or infusing in hot water the bark of the oak and pine, as well as the leaves of the sumac tree, ground and reduced to the state of a coarse powder. This decoction is concentrated to a density of about 10 deg. Beaume, and to it is added a quantity (say 15 to 30 per cent.) of cream of tartar (bitartrate of potassa) and spirit of turpentine. *Patent completed.*

2258. C. M. Westmacott. *Improvements in cements.* Dated August 12, 1862.

For the purposes of this invention, lime is combined with unburnt limestone or chalk suitably ground or reduced to powder. The proportions may be varied; but when using very good lime, it is preferred to use at the rate of two measures of unburnt chalk or limestone to one measure of lime. This compound may be employed alone or combined with sand, plaster of Paris, clay, or other materials, according to the circumstances under which it is to be used. *Patent completed.*

2259. J. Langran. *Improvements in apparatus for driving agricultural machinery.* Dated August 12, 1862.

In carrying out this invention, the inventor proposes to construct a strong framework, and to arrange in the centre of the same, in suitable bearings, a vertical shaft, the lower extremity of which is furnished with a large horizontal cogged wheel, into and underneath which a small bevel toothed wheel gears, being attached to a horizontal shaft working in bearings in the frame, and passing through the sides thereof to some distance, in order that it may be worked by a horse travelling in a circle, and turning by means of the ordinary machinery—a shaft and cogged wheel gearing into a corresponding wheel on the outer extremity of the horizontal shaft. The vertical shaft in the apparatus is furnished at its upper end with a horizontal bevel toothed wheel, into which four or more vertical bevel toothed pinions gear and operate, horizontal driving shafts passing through bearings set in standards of the framing, the ends of these shafts having driving pulleys keyed thereon, from which straps or bands may communicate motion to agricultural machines arranged in contiguity to the apparatus. A casing may be constructed on the framework so as to enclose the apparatus and protect it from the weather, leaving only the driving pulleys exposed. *Patent abandoned.*

2260. F. J. Leblond. *Improvements in sewing machines.* Dated August 12, 1862.

These improvements consist in means of sewing by the same machine—firstly, the shuttle or lock stitch; secondly, the chain stitch with one thread; thirdly, the same stitch with two threads. *Patent abandoned.*

2261. A. B. Childs. *Improvements in machinery for cutting veneers.* (A communication.) Dated August 12, 1862.

For the purposes of this invention, the log or block from which the veneers are to be cut is firmly secured to a bed-plate, by means of bolts which pass through the bed-plate and screw into the log or block. The bed-plate is perforated with holes at equal distances apart, and a sufficient number of them to receive a requisite number of bolts to hold the block firmly thereto. The bed-plate may be placed in a vertical, horizontal, or a diagonal position, but it is preferred to place it in a vertical position. The bed-plate, together with the block carried thereby, has a motion up and down a distance somewhat over and above the width of the largest block to be cut, and this motion is, by preference, communicated to it by means of two cranks and two connecting rods, one at each end of the bed-plate. The knife when making the cut is stationary, but is capable of being moved towards and from the bed-plate by the action of the feed motion, which, by means of a double ratchet, causes it to recede immediately after the cut, and again to move forward immediately before the cut a distance depending on the thickness of the veneer next to be cut. The knife consists of a straight cutting edge, with one side bevelled off, and is firmly secured to a knife-block, which is made to slide towards and from the bed-plate. A little before the edge of the knife there is a pressure-bar made adjustable by set screws, and bolted firmly in its required position to a pressure-beam. The invention also consists in the method of feeding the knife, and of graduating the feed to the different thicknesses of veneers to be cut. By this method the patentee is enabled to cut veneers more perfectly and sound, and more free from cracks, from any kind of wood, and to any thickness required. *Patent completed.*

2262. C. Sengry. *An improved smoking pipe, which may also be adapted as a tube for smoking cigars.* Dated August 12, 1862.

The patentee claims—first, the employment of a stem or tube, bent, curved, or inclined downward at one end, and communicating with the bowl, and with a detachable hollow ball, or otherwise-shaped chamber or recess, in the manner and for the purpose described; second, the mode of rendering the bowl removeable by fitting it on a pin, fork, or tongue, so as to be readily taken off and replaced, as described. *Patent completed.*

2263. G. Sanders. *Improvements in domestic fire-escapes.* Dated August 12, 1862.

In carrying out this invention, the patentee employs a chain ladder formed of two chains, in which are disposed, at distances of eight or nine inches, small plates, constituting links or parts of the chain, in which plates the ends of the steps of the ladder are fixed. A ladder so formed is very flexible, may be packed in a small space, is easily handled, and may be used as an escape from a house on fire, or for ascending or descending from a house window for other purposes. In order that it may be readily and safely available as a fire escape, he disposes it in a box immediately under the window of the apartment from which it is to be used; in the bottom of this box the upper ends of the chains are to be securely fixed, and the box is to be fixed to the floor and joists, or the ends of the chains may be at once fixed through the joists of the flooring. To the outer ends of the chains he attaches spring hooks, which, when the chain is thrown out of the window, are to be hooked into eyes previously fixed below the surface of the paving in the street, and at such a distance in front of the house as to be as clear of the fire as possible. The eyes in the street are affixed in position at the time of placing the fire escape in position in the house; and in order that they may be readily formed at any time in an emergency and kept in order, he sinks such eyes below the surface as before mentioned, and applies metal plates, in the manner of coal cellar plates, to protect them. In order that it may run out of the window freely, he disposes a roller mounted on the window sill, which may be at a suitable height, and also project from the window, to run the fire escape free it may be of a balcony below. *Patent completed.*

2264. J. Bower. *Improvements in railway sleepers.* Dated August 12, 1862.

This invention relates to a new form of iron railway sleeper, which it is proposed to make with a V shaped section, with a flange at the top of each arm, to which flange the rail is to be fastened with bolts or otherwise, whilst the angular base of the sleeper will rest in ballast in the usual way. *Patent abandoned.*

2265. J. Dickson. *Improvements in the manufacture of chlorine for commercial purposes.* Dated August 13, 1862.

In the manufacture of chlorine, according to this invention, aqueous solution of chloride of sodium, common salt, sea water, hydrochloric acid, the chlorides of iron, and other suitable chlorides, are heated and subjected in a decomposition cell to the influence of a current of voltaic electricity, whereby they are resolved into carbon at the carbon or other anode employed, while their other elements are transferred to the carbon or other cathode employed in the said decomposition cell. To separate the products of the said voltaic decomposition, the inventor employs a porous medium or mediums, although in some instances he can dispense with porous mediums. In effecting the said voltaic decomposition of the materials alluded to, he adds to the negative compartment of the said decomposition cell any suitable acid, oxide, salt, or substance which will assist the evolution of the chlorine at the anode employed. Some of the said substances, which he adds to the said negative compartment, are either nitric, nitrous, sulphurous, or sulphuric acid, or oil of vitriol, sesqui-chloride of iron, sulphate or chloride of copper, peroxide of iron or of copper. Or he obtains oxygen, either by the voltaic decomposition of acids and salts which do not contain hydrochloric acid, or by the decomposition of alkalies in the said decomposition. *Patent abandoned.*

2266. J. Dickson. *Improvements in obtaining sodium from certain sources of that metal.* Dated August 13, 1862.

This invention is carried into effect by subjecting common salt to the action of a current of voltaic electricity, applied thereto in suitable vessels, by means of carbon or other suitable anodes and cathodes immersed therein. Or the inventor subjects to similar treatment caustic, or anhydrous soda, or suitable salts of soda, when fused in suitable vessels. *Patent abandoned.*

2267. J. Cooper. *Improvements in valves and buckets for pumps, and in valves or cocks for other uses.* Dated August 13, 1862.

This invention, in so far as it has reference to buckets for pumps, consists in forming the ordinary leather packing of the bucket by binding a strip of leather round the metal, and securing it by pins passed through holes in the metal, the points or inner ends of such pins being turned down after insertion, and the leather being bevelled so as to keep the heads of the nails within the circumference of the leather packing. And this arrangement is in substitution for the ordinary mode of "cupping" the leather, and applying it to the metal by screws. And the invention, in so far as it has reference to valves or cocks for other uses, consists in the combination of the valve and seating above referred to, and in fixing the same in the tap, so that the pressure of the fluid at the inlet shall have a tendency to close the valve against the seating, the valve being opened from the seating by means of a screw or a ball lever. *Patent completed.*

2268. J. Smith and J. S. Rayment. *Improvements in apparatus for generating steam and for regulating its flow.* Dated August 13, 1862.

For the purposes of this invention, the inventors make use in the furnaces of boilers employed for the generation of steam, either of a novel form of notched fire-bar, capable of being put in motion for the purpose of rapidly and effectually breaking up any clinker that may be formed upon them; or otherwise they employ for that purpose in connection with stationary bars, a description of mechanical pricker so arranged as to enable the clinker to be rapidly and effectually broken up, so as to maintain a thorough and clear draught through the fire. For creating a draught through the bars they make use of the waste steam from the engine in such manner as to do away with the noise and irregular action upon the ordinary blast pipe arrangement. The flame and products of combustion upon leaving the boiler are further utilized by being made to pass between an arrangement of chambers through which the feed water circulates before entering the boiler. For regulating the flow of steam from the boiler, as also for regulating the admission of water thereto, and for "blowing off," the inventors employ a form of tap or cock not liable to become set fast when its parts are expanded by heat—a cause of great inconvenience with ordinary taps or cocks under like circumstances. *Patent abandoned.*

2269. J. R. and F. C. Tussaud. *Improvements in the treatment of representations formed from wax, or from compositions of wax with other matters.* Dated August 13, 1862.

The object of these improvements is to protect the surfaces of such matters by the application thereto of a coating adapted to prevent the injurious effects of atmospheric influences, and to admit of repeated cleansing thereof without the necessary disturbance of surface tints or colours. For this purpose, when the desired forms have been obtained, and any needful colouring or tinting has been applied thereto, the patentees apply to the surface thereof a coating of a suitable varnish, such as a solution of shellac, gelatine, or albumen, or white, hard, or orher varnish, preferring those varnishes which are comparatively colourless; and then in order to neutralize the glossy or shiny effect of such coating, they apply thereon one or more coatings of wax, stearine, spermaceti, or of other similar solid fatty oleaginous matters, or of the composition of which the representation is formed dissolved in benzole or other suitable solvent. *Patent completed.*

2270. C. W. Smith W. Mould, S. Cook and W. H. Hacking. *Improvements in looms for weaving.* Dated August 13, 1862.

The objects of this invention are effected—1, By an improved taking-up motion for the purpose of giving any desired number of picks to the inch, without the aid of the usual emery roller. 2, Of a positive break or strap motion, which also stops the loom in any given place. 3, By a compound weighting lever, which dispenses with three-fourths of the weight ordinarily used. *Patent abandoned.*

2271. W. L. Boyle. *Improvements in the construction of chairs and foot-stools for the use of dentists, and in chairs, couches, and beds for invalids.* Dated August 13, 1862.

In adapting the first part of this invention to dentists' chairs, the patentee attaches the back to the body of the chair by hinges at or near its lower end, and he connects the back to the arms by means of straps of leather, or by chains at both sides of the chair. These straps or chains are to be fastened by one of their ends to the arms of the chair, and by their other ends to spring rollers, or to a roller shaft concealed in the back of the chair at about the middle of its height. Upon this roller shaft is placed a notched or ratchet wheel, with a spring pawl taking into it, so as to hold it in any desired position. The head-rest is also attached to the back of the chair by a hinge or hinges of a novel construction, provided with a spring catch, whereby the head-rest may be retained in any desired position. The second part of the invention relates to a system of jointed rods or levers, together with a screwed shaft with right and left handed threads, or other mechanical means for working the levers, and thereby raising or lowering the seats of chairs or the frames of couches or beds in a perfectly vertical line. This arrangement of levers and right and left handed screws, may also be applied for raising the frames of couches and beds for the use of invalids. The third part of the invention relates to foot-stools, and consists in a simple method of altering their altitude and inclination; to which end the foot-stools are composed of two halves of a box of any suitable shape, but capable of sliding one within the other. A tendency is given to the inner one to rise by the pressure of springs contained within it, whenever the ends of certain spring levers or pawls are withdrawn from a rack or ratchet attached to the inside of the upper half of the box. The invention cannot be fully described without reference to the drawings. *Patent completed.*

2272. J. Peters. *Manufacture of hydraulic cement.* Dated August 13, 1862.

This invention relates to a certain compound for making hydraulic cement, and consists in burning in a kiln grey stone containing about 16 per cent. of clay, and 84 per cent. of carbonate of lime, and two parts of pebbles from the sea beach, or any other like stones containing about 90 per cent. of silica and 10 per cent. of clay. When burnt, they are pulverized or ground to a fine soft powder, which forms a cement ready for use. When water is added on using this cement, the lime and silica combine and become extremely hard. *Patent abandoned.*

2273. H. Twelvetrees. *Improvements in rat and mice traps.* Dated Augnst 13, 1862.

This invention consists of a long-shaped box, made wholly, or in part, of wood, zinc, tin, galvanized iron, wire, or other suitable material—that for mice being about 9 in. long by 3½ in. wide, and that for rats about 24 in. long by 8 in. wide. At one end of this box is mounted a flat tin, iron, or wood board, termed a balance board, and upon this is fixed an inclined plate, moving beyond the vertical position in either direction, and extending from side to side of the trap. Immediately above, and coincident with, the central balance of this board are two holes cut in the sides of the trap, and so disposed that, when the balance board is not acted upon, the raised inclined plate is in the same line as the two corresponding sides of the holes, and when a mouse or rat enters upon the balance board, and moves a little out of the centre thereof, as the end is depressed with the weight of the animal, the slanting plate falls in a line with the other sides of the entrance holes, thus preventing his return, and compelling him to go forward into the body of the trap. Underneath the balance board is fixed a plate of tin, or iron, extending between the two sides of the trap to prevent the vermin from making their escape in that direction. By preference, the patentee allows the whole, or a portion, of the width of the entrance holes to be left open across the top of the trap, so that the vermin may enter either at the top or at the sides. He also forms the entrance end of perforated zinc or open wirework, and inside this end of the trap, upon the surfaces which can be seen through the openwork end, he fixes some corn seeds, or other bait. Inside the trap, at the end of the balance board which falls down, he disposes a tin, iron, or zinc plate, from side to side; upon this plate he fixes some small hooks, for attaching suitable food, to act as a bait for the vermin, and thus they are compelled to step upon the balance board to reach the bait; the instant they move out of the centre thereof the end falls down with their weight, and, finding they cannot return, owing to the slanting plate having closed the entrance holes, they pass forward, and the same instant the balance board returns to its original position. *Patent completed.*

2274. G. Turner. *Improvements in fastening armour plates of ships.* Dated August 13, 1862.

In fastening the armour plates of ships, the inventor prefers to form the plates with two longitudinal ribs throughout their length, such ribs to be some little distance from the edges of the plate, and of about 4 in. in breadth, and 1 or 2 in. in thickness, that is to say, they project about 2 in. from the back surface of the plate. In these ribs he bores holes for the reception of the bolt ends or heads; these holes being bored from the inside, and sunk to about the thickness of the rib, do not enter the general substance of the plate, or detract from its strength. The plates may be of 3, 4, or 5 in., or of other suitable thickness. The holes so bored he undercuts, that is to say, enlarges inwards, to a conical form the shape which the bolt head or end is made to assume. Instead of ribs being formed on the plates, bosses or thickness pieces may be welded on in the positions required for the bolts, or the undercut holes or recesses may be made in the body of the plate itself, but this somewhat weakens the plate, which it is better to avoid. In this case he sinks the holes about 1¼ or 1½ in. in depth. The ship's side being prepared to receive the ribbed plates, that is, with grooves into which the ribs fit, the bolts are driven through from the inside, the bolt being a rod of iron fitted with a screw or other means of fastening inside the ship, while the head part has cross saw cuts made in it, but which otherwise is of the form of the round bar of which it is formed. For inserting the bolt, the point of a cross wedge is inserted in the saw cuts, and fixed there by a small pin; the bolt is then driven through the ship's side into the recess or hole in the plate, the cross wedge retains its position until it comes in contact with the bottom of the hole, where it stops, and the bolt is further driven home, so that the cross wedge opens out the saw cuts and swells the end of the bolt out to fill the enlarged internal form of the hole, and assuming a conical form therein, it cannot again be withdrawn, as any force applied to draw it out brings the wedge with it, and so keeps the bolt end of the enlarged conical form it has assumed. The bolt so inserted and fixed in the plate is then screwed up by its nut, or otherwise fixed, and so on the several bolts are inserted throughout the area of the plate. The projecting ribs or bosses when made on the plate remove all its weight from the bolts, which, in that case, have no other strain than that necessary to hold the plate against the ship's side. Instead of a cross wedge a single wedge might be used, but would not be so well adapted for the purpose required. The plates fitted and secured according to this invention, may be further tongued and grooved together as in ordinary. *Patent abandoned.*

2275. L. D. Verstraet and E. M. Olivier. *Improvements in manufacturing carbonate of soda.* Dated August 13, 1862.

The patentees claim—1, The formation of carbonate of soda by transforming sulphuret of sodium into bicarbonate of soda, whatever may be the manner in which the sulphuret of sodium is obtained, as described. 2, The employment of lime or other oxydated agent capable of answering similar purposes. 3, The arrangement of furnace and other apparatus represented in the drawing. 4, The formation of carbonates of potash and soda by transforming sulphurets of potassium and sodium into bicarbonates of similar bases. 5, The preparation of sulphurets of potassium and sodium by the decomposition of sulphuret of barium. 6, The manufacture of sulphate and carbonate of baryta in a similar manner. 7, The application of a gas apparatus of any suitable form for producing the combustion of the hydro-sulphuric acid, and for transforming it into sulphuric acid. 8, The use of steam for quickening the reactions. 9, The entire apparatus, which may be of any suitable form and arrangement, for the transformation of the sulphuret of barium into carbonate, and also for producing the combustion of the hydro-sulphuric acid, in order to transform it into sulphuric acid, and also the various modifications and improvements therein necessary for producing the desired result. *Patent completed.*

2276. L. Galli. *Improvements in apparatus for propelling vessels.* Dated August 13, 1862.

This propeller consists of two paddles, which are placed below the water line, and, by preference, near the stern of a ship, and which are moved to and fro in the direction of the length of the vessel. They are jointed to a metal frame which is moved to and fro in guides in a slot or rectangular opening in what is called the "dead wood;" this movement is given to the frame, and so to the paddles, by a hollow rod or shaft reciprocating in the direction of the length of the keel. The stroke of the shaft when in motion is proportioned to the size of the ship, and is effected by means of a crank and connecting rod, which are adapted to the engine. The paddles are open, so as to project from the sides of the keel when they are going in the direction opposite to the intended movement of the vessel, and shut so as to be within the opening in the keel in the return movement. The shutting and opening of the paddles is effected a few moments before the change of the direction of these movements by two rods which pass through the hollow shaft, each paddle being connected to one of the rods. When it is desired to reverse the direction in which the vessel is propelled, the paddles are (by the rods which pass through the hollow shaft) caused to be open when the shaft is moving in the direction in which it was moving when they were before shut, and to be shut when they were before open. *Patent abandoned.*

2277. W. Schnell. *Improvements in extracting the sulphur or sulphurous acid from the oxy-sulphuret of calcium which is contained in the residues or waste material obtained in the manufacture of soda.* Dated August 13, 1862.

The waste material is, in carrying out this invention, moistened with water, and then spread out upon great hurdles superposed one upon another, in the same manner as those used in a common drying room. The principal condition is the unrestrained access of air combined with some steam, water, and carbonic acid, if this is to be found. The material remains upon the hurdles for about two or three weeks (but not more than a month); after removing it from the hurdles it is washed out (in an apparatus fit for the purpose) with water never exceeding a temperature of thirty to forty centigrade (of Cilsius), and a solution of hyposulphite is thus obtained. When this solution has been removed, the material is again spread out upon the hurdles, and after the required time washed out again till no more hyposulphite will be found. Treated in this way, the residue or waste material acquires more weight during its stay upon the hurdles. This augmentation of weight is equal to the whole weight of the hyposulphite formed; and it results therefrom that, if the waste material contains 5 per cent. of sulphur to be gained from the hyposulphite, the weight of the sulphur is equal to 6 per cent. of the primitive weight of the waste material used; after having repeated the above-named process twice, the inventor has therefore obtained 12 per cent. of sulphur. The hyposulphite of calcium thus obtained must now be decomposed, and this will be done by using muriatic acid in the following manner:—The solution of hyposulphite is boiled in an iron boiler, and while boiling the muriatic acid is to be added by degrees, and the solution kept boiling till the sulphur is separated from the sulphurous acid, which is then let off, and the sulphur will be found at the bottom of the boiler in a pure state. If he wishes to obtain sulphur alone, the hyposulphite of calcium is evaporated by heating till dry, and then distilled by heating in iron retorts. By thus proceeding he obtains half the sulphur contained in solution, and the residue remaining in the retorts contains a mixture of sulphite of calcium and sulphuret of calcium. If he wishes to obtain sulphurous acid only, the solution, when evaporated as before, is to be heated in furnaces with air unrestrained access of air, and half the sulphur which the solution contains is obtaining as sulphurous acid, and the residue left in the furnace is entirely composed of sulphate of calcium. *Patent abandoned.*

2278. J. H. Johnson. *Improvemnnts in carts and other vehicles.* (A communication.) Dated August 13, 1862.

This invention relates to certain improvements in carts and other vehicles, with the view of making them capable of weighing their own loads. According to this invention, the body of the vehicle is made independent of the framing when weighing a load, and solid with it when simply transporting the load. Toward the back of the framing there is, according to one arrangement, a transverse shaft, to which a forked lever is attached, and this lever, at its fore end, presses during the process of weighing upon one arm of a Roman balance placed in front of the vehicle, and attached thereto. Regulating screws, attached to the framework, are made to support the body during transit, but when the operation of weighing is to take place these screws are lowered, and the body of the vehicle is then thrown upon the forked lever, which acts, as before mentioned, on the weighing apparatus. *Patent completed.*

2279. E. J. Dagnal. *Tray or receptacle adapted for washhand stands for holding tooth brushes, tooth powder, and nail brushes.* Dated August 14, 1863.

This invention is designed to prevent the unpleasant odour which tooth brushes acquire when kept in a covered box or tray of the ordinary kind. It is, by this invention, proposed to effect this object by so making a tray or receptacle that the tooth brushes shall stand upright therein, somewhat similar to an umbrella stand; a recess is formed therein to contain tooth powder, and a cover is adapted thereto. The lower part may be used to hold a nail brush. Trays or receptacles constructed on the above plan may be made very ornamental, of various devices, in porcelain, glass, or other material, or a combination of materials. *Patent abandoned.*

2280. A. Walker. *An instrument to determine or ascertain the depth of water and the distance a ship has run.* Dated August 14, 1862.

This invention consists of a tube which surrounds, or partially surrounds, an archimedean screw, or one, two, or more fans, or a wheel like the paddle-wheel of a steamboat, or any other suitable revolving power communicator which is capable of being actuated by water passing through the tube, and which is connected with a train of indice wheels, enclosed in a case, placed on the outside of the tube, and which indicate the distance a ship has run and the depth of water sounded. When the instrument is used for sounding, a weight is attached to the bottom of the tube to facilitate the sinking thereof. The propeller inside the tube revolves by reason of the action of the water, passing up through the tube, acting against the blades of the propeller, and, when used as a log, by being drawn horizontally through the water by the velocity of the ship. In the latter case the weight is dispensed with. The quantity of water acting upon the propeller may be regulated by the size (diameter) of the tube, or by the size of the screw, or other form of power communicator. *Patent completed.*

2281. J. Irvine and J. W. Hand. *An improved rifle rest.* Dated August 14, 1862.

This invention is carried out as follows:—A trough of wood, lined with india-rubber, is fixed on a ball and socket joint, which ball and socket joint is mounted on a vertical rack, the rack sliding in a hollow pillar, or upright, fixed on the base of the instrument. The trough of wood is of a shape proper to receive and support the rifle from the lower band to the trigger-guard, and the rifle is fixed in the said trough by means of a screw on one side, which screw carries at its end a spring which, by the action of the screw, is made to press against the rifle, and bind it tightly on the trough. The ball and socket joint is provided with a clamp screw, for fixing it in any required position, and the rack, which carries the ball and socket joint and trough, is raised and lowered by means of a pinion in the pillar, or upright, which pinion is worked by a handle on its axis. The rack is also provided with a clamp screw, so as to fix it in the required position, as well as a pall, or click, which engages in the teeth of the rack, and prevents the descent of the rack after it has been lifted by the pinion. The said pall, or click, can be disengaged from the rack by pressing on a thumb-plate when it is required to lower the said rack. The pillar, or upright, is connected to the base, or platform, by strong iron stays and bolts, and the platform is made to fold up and form a box, in which the pillar and other fittings can be packed. In using this new or improved rest, the rifle is placed in the trough by means of the screw and spring before described. The elevation and direction of the rifle are adjusted by means of the ball and socket joint, which is fixed by its clamp screw, and the rifle is raised or lowered to the required height of the shoulder of the shooter by means of the pinion and rack, and the rack afterwards fixed by its screw. The rifle may be fixed and adjusted in our rifle rest in a few seconds. *Patent abandoned.*

2282. J. Key and E. Hoskins. *Improvements in plain and ornamental metallic pillars for bedsteads, cots, couches, &c.* Dated August 14, 1862.

In carrying out this invention, the inventors make a mould in cast iron, or other suitable material, the said mould having internally the figure of the ornamental pillar to be made. The mould is made in two or more pieces. They place a rod or tube of iron, or a plain pillar, in the axis of the mould, and pour into the mould plaster of Paris, or other mixture or composition which will dry or set hard. There is thus made a core, which they place in another mould of the same figure as that in which the said core was made, but somewhat larger in diameter. They then pour melted metal into the last-described mould, so as to fill up the space between the mould and the core with the melted metal. A hollow metallic pillar, having the same ornamental figure as the interior of the outer mould, is thus produced. In making plain metallic figures according to this invention, they proceed in the manner described with reference to an ornamental pillar, excepting that they use moulds having a plain instead of an ornamental figure. *Patent abandoned.*

2283. G. Welch. *Improvements in inkstands, metallic pens and penholders, and other instruments and appliances used in writing and marking.* Dated August 14, 1862.

We cannot here give space to the details of this invention. *Patent completed.*

2284. C. E. Wilson. *Improvements in buskle fastenings for braces and belts.* Dated August 14, 1862.

This invention consists in forming a box or hollow case on the bottom of the flap of the buckle, to receive a spring catch formed in a piece with or fixed to a plate to which the brace ends, in the case of braces, or one end of the belt, in the case of belts, are, or is attached. Instead of unbuttoning the tabs on the brace ends, as at present, the brace is released by withdrawing the spring catch from the case on the buckle flap. The brace is attached by simply inserting and engaging the catch in the case. *Patent abandoned.*

2285. W. Beatson. *Improvements in stoves.* Dated August 14, 1862.

This invention consists in constructing drawing-room and other stoves with the inner arch and cheeks, together with the brick or other back and the bottom grate and the doors into the chimney, moveable, either separately or two or more of such parts together, being those parts which are liable to be injured or blackened by the action of the fire. The removal is effected without the necessity of moving the stove from the chimney-piece. The object of the invention is to afford more ready access to the chimney, for the purpose of affixing or refixing and sweeping or repairing the said stoves; also to enable the aforesaid parts to be taken out when the fire is not required, and to have bright or ornamental parts substituted or placed in front of the parts blackened by the fire, without removing the parts so blackened. *Patent completed.*

2286. G. White, F. Buckland, and C. Rees. *Improvements in water-closets.* Dated August 14, 1862.

For the purposes of this invention, the basin of the closet—which may be made either of glazed pottery, earthenware, enamelled iron, or other suitable material—is constructed with the bottom of a concave form, so as always to retain it in a sufficient quantity of water. The basin is constructed nearly of the same width at the bottom as at the top, and the sides being thus nearly perpendiular to the water's edge, are not liable to be fouled by offensive matter dropping and lodging upon them, the deposits in the basin falling into the water at the bottom. The outlet from the basin is made by an aperture at the side, at such a distance from the bottom as to retain the necessary quantity of water, while the inlet admitting the water from the cistern is placed opposite the discharge aperture, and the quantity of water admitted is regulated by a fan, so shaped as to cleanse the basin thoroughly by allowing a portion of the water to be driven on each side of the basin, instead of being carried with a spiral motion round it, as is usually the case, whilst the bulk of the water flows across the bottom of the basin into the discharge pipe. The basin is trapped by means of a syphon or trap in the usual manner. The closet is so constructed by means of a suitable combination of rods and levers connected with the seat and service box as be self-acting on every occasion of the closet being used, and thus preventing the possibility of use without the removal of the contents of the basin, as hereinafter described. *Patent completed.*

2287. D. P. Marques. *Improvements in apparatus for cleaning the bottoms of ships.* (A communication.) Dated August 14, 1862.

This apparatus is formed of two metal foundation plates, one of which supports two cylinders and pistons, the other being provided with a strong brush or scraper. These plates contain also a space enclosed by a sheet of india-rubber or gutta-percha, which space communicates with a force-pump on the deck of the vessel by means of india-rubber tubes. The piston-rods from the cylinders are attached to the brush or scraper, and the cylinders are supplied with compressed air from the pump by means of tubes, by which means a lateral reciprocating motion is given to the brush or scraper, which is pressed firmly against the sides of the vessel by means of the pressure of air in the space enclosed by the india-rubber. *Patent completed.*

2288. H. R. Passey and L. Niman. *Improvements in cigar tubes or holders.* Dated August 14, 1862.

This invention consists of an improved tube or holder for cigars, by the use of which the cigar may be smoked without being brought in contact with the mouth or fingers, and whereby the cigar may be extinguished at any time, and transferred to the pocket or the travelling case perfectly enclosed in the tube, and incapable of imparting an unpleasant odour to any contiguous articles. *Patent abandoned.*

2289. J. Petrie, jun. *Improvements in apparatus for blowing and exhausting air.* Dated August 14, 1862.

In carrying out this invention, the inventor adopts fixed blades between fixed surfaces, leaving the circumference open for the passage of air, which is drawn through a central aperture. The revolving blades he mounts upon a shaft having a bearing on one side only, and extending through one of the fixed surfaces, which surface is formed upon or is carried by the pedestal constituting a bearing for the shaft. Also he adapts fixed vanes outside the revolving vanes extending concentric therewith. *Patent abandoned.*

2290. W. J. Curtis. *Improvements in apparatus for ascertaining the fares and earnings of public vehicles.* Dated August 14, 1862.

In adapting this invention to a cab or omnibus, the inventor provides a packet of cards, having on their face a graduated dial, numbered and representing distances in miles, half miles, and quarter miles, if necessary. Each omnibus passenger or hirer of a cab will receive one of these cards on entering a vehicle, it having been pierced by a punch to indicate a starting point on the dial. On leaving the vehicle, the card is to be again pierced, and the distance between the two nicks in the card will show the distance traversed. The punch will, however, when making the second nick which indicates the termination of the passenger's journey, strike out a portion of the card, and discharge it into a receiver, which is accessible only to the proprietor of the vehicle. This punched out portion will have a counterpart of the nicks retained by the passenger, and will, therefore, show the amount of the fare chargeable to the passenger. *Patent completed*

2291. J. Hopwood. *Improved apparatus used for collecting fibrous material and dirt from the carriage boards and roller beams of mules and other similar machines used in spinning.* Dated August 14, 1862.

In carrying out this invention, the patentee employs a roller, or series of rollers, extending along the carriage board, revolving in contact therewith, while the carriage is running out, but kept clear therefrom when the carriage is running in. This change is effected by mounting the said rollers upon levers turning on centres at the back of the roller beam, and connected to other levers, which are fixed to a line shaft, extending along the width of the mule. One or more of these last-mentioned levers carries a roller, which, when the carriage is running out, moves beneath an inclined plane, which inclined plane then turns upon a centre, so as to allow the said rollers to pass on to its upper side, and thus the line shaft is caused to turn and elevate the cleaning rollers. To the levers which carry the cleaning rollers he adapts arms extending upward, and carrying a roller or rollers, which, as the carriage runs in, move upward and revolve against the roller beam, but when the carriage runs out, then the turning of the levers upon their centres conveys the said rollers clear of the roller beam. *Patent abandoned.*

2292. J. Hearne. *Improvements in apparatus or appliances to be used in the treatment of hospital and other patients.* Dated August 14, 1862.

This invention consists in the application of a framework which is mounted over the bed of the patient and furnished with a system or series of cords which are conducted over suitable pulleys carried by the framing; the ends of these arms are pendent over and distributed around the area occupied by the patient. The free ends of the cords are conducted and fastened to a double-armed lever mounted on the end standards, by which lever power can be applied to any number of the cords simultaneously to lift any weight attached to the opposite ends. The patentee disposes the pendent cords in pairs one at each side of the head, one at either shoulder or across the back, one at either side of the loins or thighs, and one at either side near the feet—in all eight, but this number may be varied. One or more pairs of these suspending cords may be arranged separate independently from the lever before mentioned, so as to permit a greater or less lift for the head and shoulders, or other parts of the body that may be necessary. Suitable pawls and ratchets or other means are provided for fixing the lever or hand bar in position when the patient is raised, to which bar a single pair of cords only may be attached. The pendent cords are provided with hooks or other means of easy attachment, to which bands or cradles, in which parts of the body are supported, may be applied. This system of support is also applicable for support of the bed-clothes of a patient or other articles that may be necessary to be supported independently of the bed. The upper horizontal framework is carried on standards raising it sufficiently above the bed for all purposes that may be required. This apparatus might also be supported from a bedstead having an overhead framework, but he preferred to make it complete in itself. *Patent completed.*

2293. W. Soulter. *Certain apparatus for raising and planishing metals.* Dated August 14, 1862.

We cannot here give space to the details of this invention. *Patent abandoned.*

2294. W. B. Herapath. *Improvements in decolourizing solutions of sugar.* Dated August 14, 1862.

For the purposes of this invention, the inventor adds to the solution or juice a small portion of the hydrochlorite, of an alkali, or of an alkaline earth, that which he prefers being the hyperchlorite of lime or ordinary bleaching powder; this he dissolves in water, and he adds the solution to the saccharine juice or solution of sugar. Afterwards he can separate the lime by the addition of phosphate of soda and potash, which converts it into an insoluble phosphate of lime, which is separated by filtration. *Patent abandoned.*

2295. J. S. Blockey. *Improvements in the manufacture of colouring matters.* Dated August 14, 1862.

For the purposes of this invention, the inventor adds to aniline or its homologues, a mixture of nitric and hydrochloric acid, and he maintains this compound for some time at a temperature of about 180 deg. Fah., and thus he obtains the colours required, viz., a mixture of red, purple, and blue, the proportions of which will vary according to the quantity of the acids employed. The colours contained in the mixture may be separated the one from the other and purified. *Patent abandoned.*

2296. W. B. Herapath. *Improvements in treating crystallizable sugar to render it more suitable for fermentation and conversion into alcohol and vinegar.* Dated August 14, 1862.

This invention consists in preparing cane, beet, or other crystalline sugar of like character, so that its fermentable properties shall be greatly increased, and the process of fermentation rendered more certain and constant thereby, and the inventor treats it in the following manner:—He dissolves the sugar in hot water, either previously or subsequently acidulated with tolerably pure hydrochloric acid (but more especially rendered free from all contamination with iron); and having raised the temperature of the mixture from about 180 deg. Fah. to 212 deg., and kept it at that temperature during two or three hours, more or less, he neutralizes the acid by adding to the mixture a sufficient quantity of carbonate of soda, carbonate of potassa, lime water, milk or cream of lime, carbonate of lime, or any other suitable substance; and if no excess of these neutralising agents has been improperly applied, the solution will be immediately in a fit state for undergoing the process of fermentation, without undergoing any further change than the simple reduction of the temperature and gravity to those points at which the process is usually begun in the brewing trade. But if the colour of the sugar employed has been dark or high-coloured, it might be necessary, for some purposes, to further submit it to a decolourizing or bleaching process, so as to render it sufficiently free from colour to be serviceable for the end in view. *Patent completed.*

2297. G. E. Spagnoletti. *Improvements in the manufacture of apparatus for signalling trains on railways.* Dated August 14, 1862.

For the purpose of signalling trains on railways from one point to another when a train passes, and when the line becomes clear, the patentee employs instruments each having a dial and two finger-keys. In connection with the dial is a magnetic needle, surrounded with coils of insulated wire, and having mounted on it two screens; on one of these are written the words "line clear," and on the other the words "train on the line;" and the screens are so arranged in connection with a hole in the dial-plate behind which they work, that when the needle inclines to one side, the notice on the screen on one side of the needle becomes visible, and similarly when the needle inclines to the other side, the notice on the other side is read. The screen with the notice "line clear" he colours white, and the screen with the notice "train on the line" he colours red, so that the signalman may readily see from a distance how the needle is standing. The finger-keys of the instrument are similarly coloured, and the parts are arranged so that depressing the red finger-key will make such contact as will cause a current of electricity to pass from the battery which works the instrument through the coils around the magnetic needle in such a direction as to cause the said needle so to incline as to show the words "train on the line" on the red screen. By depressing the white finger-key, a current of electricity will be similarly caused to traverse the coils, so as to cause the needle to incline in such a manner as to show the words "line clear" on the white screen. *Patent completed.*

2298. M. A. F. Mennons. *An improved apparatus for the production of sealing wax impressions.* (A communication.) Dated August 15, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2299. J. Barclay. *Improvements in machinery for the manufacture of nails.* Dated August 15, 1862.

This invention consists—1, In the mode of heading and pointing nails made from wire. 2, In the mode of cutting off short-pointed strips, the length of the nail from sheets of metal, and in the use of pressure rollers for consolidating the said short strips and making same into nails. To manufacture nails from wire, the patentee employs four levers—two working horizontally, and two vertically; the end of each pair of levers operate so as to squeeze the wire to a point, and are operated upon by slides and rollers. The heading operation is performed by a sliding heading tool; a revolving plate, fitted with spring sliding holders, takes the pieces of wire from the heading tool, and carries them successively opposite to the pointing tool. Expanding dies, operated upon by a screw for opening and closing the same, are employed to hold the wire whilst it is advanced and cut off to the desired length to form a nail. He also proposes to employ a circular piece of metal or table suitably held, and capable of being moved about its axis of motion, so that, supposing a strip of sheet metal of the width of the required length of the nails to be made therefrom to be placed on the table, and the table to be moved about its axis of motion by suitable self-acting mechanism, the said strip, instead of being presented square to the cutters, is inclined thereto sideways, and then cut; the strip is afterwards moved in an opposite direction, and again cut, the effect of which is to cut strips of a wedge form instead of with parallel sides, or, in other words, to cut the strips pointed. The heading operation is effected by a bent lever operated upon by a cam, each nail being held by expanding dies operated upon by sliding pieces of metal formed with inclined or wedge shaped ends. Each strip of metal cut off the main strip falls upon a vibrating piece of metal formed with two sides, which throws the cut pieces alternately down two channels formed in a casting, thence they pass between the pressure rollers before referred to, where they get consolidated, and finally are taken hold of by the expanding dies, and held thereby during the heading operation. The above machinery is designed to be double-acting, that is to say, whilst one nail is being headed on one side of the machine, the other side of the machine is discharging a finished nail. *Patent Completed.*

2300. A. Sheppard. *Improvements in obtaining light.* Dated August 15, 1862.

This invention has for its object improvements in obtaining light by combining oxygen gas or carbonic oxide at or near the point of combustion with vapour of naphtha or other hydro-carbon oil for the purpose of obtaining light. *Patent abandoved.*

2301. T. Carvin. *Improvements in screw propellers.* Dated August 15, 1862.

This invention consists of certain improvements in screw propellers, whereby the pitch of the blades may be more readily adjusted and fixed than by the methods at present in use, and by the application of which to vessels a greater speed can be obtained than by the ordinary propellers. The patentee forms the blades of the propellers of an irregular oval outline, the blades being bent or bowed so as to form a curvilinear surface to act upon the body of water in contact therewith, whereby the water may be gradually and easily displaced, and the vessel propelled without any sensible vibration being caused by the propeller. In some cases he prolongs or extends the extremities of the blades, so as to form their outline of an elongated irregular oval. *Patent completed.*

2302. T. F. Kirby. *Improvements in garments for gentlemen and ladies' wear.* Dated August 15, 1862.

This invention consists in certain improvements—1, in garments for gentlemens' wear, having for their object the combination of the vest and coat, in order to form one garment of the two; and, 2, in mantles, cloaks, capes, or jackets worn by ladies, the object of which is to attach an interior body fastening in the front, forming of the two one garment, on the same principle as in the first instance. *Patent completed.*

2303. J. Newman. *Improvements in machinery for the manufacture of metallic tubes.* Dated August 15, 1862.

This invention has for its object improvements in machinery for the manufacture of metallic tubes, whereby several tubes are capable of being drawn at the same time by one drawing head or bench, in place of drawing such tubes singly, as heretofore practised; the invention being particularly applicable to the drawing of solid metal tubes of comparatively small bore, suitable for being employed in the construction of locomotive and other steam boilers. For this purpose, in place of connecting each tube and mandril (where a mandril is used) to a separate draw chain or other draft instrument, the inventor causes a series of tubes with their mandrils (when such tubes are of comparatively small diameter) to be connected in any convenient manner to a draw bar or cross head, which moves to and fro on fixed guides. Motion is given to the draw bar or cross head by a chain or otherwise, in order to draw the tubes through the openings in the draw plates, which are fixed and arranged in a series to correspond with the tubes, such draw plates being of the ordinary construction. *Patent abandoned.*

2304. J. Carter and J. Maher *Improvements in power looms.* Dated August 15, 1862.

The object of this invention is to simplify the construction of the parts for working the shuttle boxes of power looms, and to bring them severally as required into line with the open shed. To this end, the patentees cause the levers from which the shuttle boxes are suspended to rock and raise the boxes by motion obtained from the main driving shaft, and they effect the tripping of these levers, so that they may fall and let down the boxes from a motion derived from the same main driving shaft. The shuttle boxes they lift by means of eccentrics or cranks on the driving shaft, which are connected by straps to a pair of catch rods, and by their rotation give an up and down motion to those rods. The catches of these rods are intended to take into pins projecting from the sides of the shuttle-box levers when the boxes are to be raised, and on their descent to rock the levers and elevate the boxes. When, however, it is desired that no such action shall take place, the eccentric catch rods are allowed to be brought forward by a spring, so that in their descent, actuated by the eccentrics, the hooks on their upper end, and on the right hand will pass by the pins of the box levers. By this means the hooks on the left hand side of these rods are brought over the disengaged ends of the pendent catches (which act as stops to the shuttle-box levers, and maintain the shuttle boxes in their different positions), and press the catches to a different position on the box lever, so as to allow the shuttle box required to come into line with the open shed. The reversing motion is obtained by the agency of two eight-sided star wheels, on a small cross shaft, supported in the top rails of the loom. These star wheels are different in size. On the top of a shaft (driven from the main shaft by toothed wheels equal in size) are two circular surfaces to correspond with the star wheels, and ,as the one or the other is in position, a back or forward motion is given to the chain box. *Patent completed.*

2305. J. H. **Johnson.** *Improvements in electro-magnetic time keepers.* (A communication.) Dated August 15, 1862.

This invention relates to a peculiar construction and arrangement of what the inventor terms a galvanic chronometer, with centrifugal regulator, and consists—1, of a peculiar construction and arrangement of electro-magnetic machine for actuating the works of the chronometer, and of which it forms a part; and, 2, of a peculiar construction and arrangement of centrifugal regulator for controlling the speed of the electro-magnetic machine, and thereby regulating the movements of the chronometer. *Patent completed.*

2306. R. **Barclay.** *Improvements in chronometers and other time keepers.* Dated August 16, 1862.

This invention comprises improvements in the escapement details of chronometers and other time keepers, and in the details by which the force of the spring is communicated to the wheelwork. The first portion of the improvements is applicable to the kind of chronometer escapement in which springs requiring extremely delicate adjustment have heretofore been used, and consists in causing the lever or vibrating bar acting as the detent or pallet of repose, instead of being actuated through a delicate spring, to be acted upon in one direction by a second rigid arm or lever, jointed or connected to it in such a way as to be free to move away from it in the other direction. The second portion of the improvements relates to an arrangement dispensing with the chain by which the force of the spring is ordinarily communicated to the fusee. *Patent abandoned.*

PROVISIONAL PROTECTIONS.

Dated Oct. 23, 1862.

2851. J. T. Stroud, Birmingham, lamp and chandelier manufacturer. Improvements in lamps for general and special purposes, and in parts connected with the same.

Dated Nov. 11, 1862.

3039. H. Burridge, 15, Grenville-street, Brunswick-square, builder. Improvements in apparatus for extinguishing fires; applicable also for ventilating and fumigating, and for supplying, delivering, and distributing fluids.

Dated Dec. 29, 1862.

3489. W. Billinghurst and J. Requa, Rochester, New York. An improved portable battery.

Dated Jan. 6, 1863.

49. J. Eckersley, Westhoughton, Lancaster, mechanic. Improvements in looms for weaving.

Dated Jan. 9, 1863.

83. W. Tasker, Waterloo Iron Works, near Andover, engineer. Improvements in the construction of harrows.

Dated Jan. 19, 1863.

165. B. V. der Mark, 8, Great John-street. Manchester. A new and improved musical instrument of the harmonica class.

Dated Jan. 26, 1863.

230. A. L. Liétout, Paris, doctor of medicine, and J. B. Roisin, 56, Rue de Sablonville. Improvements in gymnastical apparatus.

Dated Jan. 31, 1863.

285. J. Lightfoot, Accrington, chemist, and F. Trachsel, Manchester, chemist. Improvements in machinery or apparatus used in the process of distillation.

Dated Feb. 4, 1863.

320. C. F. and D. Faulkner, Birmingham, gun-barrel manufacturers, J. Fairley, Birmingham, commercial agent, and W. C. Stiff, Edgbaston, military gun inspector. Improvements in the manufacture of gun barrels.

Dated Feb. 7, 1863.

347. C. Parigot and A. Grivel, 29, Boulevart St. Martin, Paris, civil engineers. Improvements in locks.

Dated Feb. 12, 1863.

379. F. Oppenheim, 379, Strand. An improved plastic compound for dental purposes, to be used instead of wax, gutta percha, or resinous gums, in taking the impression of the mouth. (Partly a communication.)

Dated Feb. 13, 1863.

388. J. Jones, Liverpool, lead merchant. Improvements in the manufacture of lead, tin, and other metals, or amalgamation of metals of a like fusible nature, into sheets of any required thickness and length, and also coating one or both sides of pipes and sheets of lead, and other metal, or amalgation of metals, with tin or other substances, and in the apparatus connected therewith.

390. J. Robertson, foreman printer, Levenbank Print-works, Dumbarton. Improvements in apparatus or means for printing woven fabrics by blocks.

392. W. Robertson, Manchester, mechanical engineer. Improvements in machines for spinning and doubling.

393. G. Wrigley, Dukinfield, machine maker, and S. Morris, mechanic. Improvements in machines for spinning and doubling.

394. O. H. Hodge, Shoreditch, hat maker. Improvements in hat brims, in the manufacture of hat brims, and in the apparatus or machinery used in such manufacture.

396. S. Whitaker, Craddock-street, Haverstock-hill, electrician. Improvements in indicating the positions or conditions of railway signals and points, and in the apparatus employed therein.

Dated Feb. 14, 1863.

398. R. Baguley, Greenlow Mill, Blackburn, shuttle manufacturer. Improvements in the construction of creels for warping machines, and other machines to which creels are applied.

400. W. C. Paul and A. T. Shore, Queen's-road, Bayswater, upholsterers. Improvements in the mode of constructing spring mattresses and other such articles for sitting and reclining upon.

401. J. S. Gisborne, Birkenhead, electrical engineer, and W. Simpson, Liverpool, gentleman. Improvements in means for rendering ships' and other compasses insensible to local attraction.

402. H. Dembinski, 13, Rue de l'Oratoire du Roule, Paris, general. A new motive apparatus and processes proper for giving to it a continuous motion and unlimited strength.

404. W. Wood, Ashton-under-Lyne, manager. Certain improvements in cutting or producing screws or threads, and in apparatus connected therewith.

406. J. H. Walsh, Kensington. Improvements in breech-loading firearms, and in the cartridge cases to be used therewith.

408. W. Clark, 53, Chancery-lane, engineer. Improvements in the method of, and apparatus for, separating the fibres of straw, wood, and other vegetable substances, and extracting the gummy and colouring matters therefrom, to render them fit for paper stock, or for other purposes. (A communication.

410. J. and H. Higgins, Salford, machine makers. Improvements in carding engines, and in apparatus connected therewith.

412. J. Morgan, 23, Stephen's-green North, Dublin, Esq., F.R.C.S.I. Improvements in embalming and preserving from decay human bodies and bodies of other animals; also pickling, curing, and flavouring animal bodies.

Dated Feb. 16, 1863.

416. C. D. Abel, 20, Southampton-buildings, Chancery-lane. An improved omnibus. (A communication.)

418. J. B. Watts, Birmingham, sword and bayonet manufacturer. Improvements in the manufacture of matchets and swords.

420. R. A. Brooman, 166, Fleet-street. An improved cover or protection for steel and other metal springs, ribbands, and hoops. (A communication.)

422. J. H. Haywood and W. Vernon, Nottingham, lace manufacturers. Improvements in packing bonnet fronts, rouches, and other similar articles.

424. W. Nalder, Challow Works, Wantage, Berks, engineer and agricultural implement manufacturer. Improvements in rotary screens, and in the machinery or apparatus employed in the manufacture of such screens.

Dated Feb. 17, 1863.

426. T. W. Salmon, Mile-end Old Town, mechanic. Improvements in washing machines.

428. W. T. Dibb, Hull, brewer. An improvement in brewing.

430. J. Gimson, Leicester, mechanical engineer. Improvements in presses for punching or cutting out leather and other substances.

432. J. Durant, Sussex-street, St. Pancras, engineer. Improvements in chimney tops.

434. J. W. Lane, Caledonian-road, watchmaker. Improvements in fastenings for studs, sleeve fasteners, solitaires, bracelets, brooches, and other uses.

436. H. Tomlinson, Rotherham, stove grate manufacturer. Improvements in stoves or fireplaces for warming apartments.

Dated Feb. 18, 1863.

438. E. Strawson, 9, Royal Arcade, New Oxford-street. Improvements in the manufacture of buttons, which may be instantaneously attached without sewing.

439. G. K. Geyelin, civil engineer, 13, Chenies-street, W.C. An improved grate, whereby the perfect combustion of the various compounds of coal is produced.

440. M. Siégrist, Ewell, gentleman. An improved atmospheric brake or break.

442. J. F. Spencer, Newcastle-upon-Tyne, consulting engineer. Improvements in apparatus for regulating and working the valves of steam and other engines.

444. F. Johnston, manufacturer, and R. Heatley, overlooker, Blackburn. Certain improvemehts in looms for weaving.

446. G. T. Bousfield, Loughborough-park, Brixton. Improvements in breech-loading firearms. (A communication.)

Dated Feb. 19, 1863.

452. T. Markland, Hyde, and J. C. Dickinson, Blackburn, machine maker. Certain improvements in machinery or apparatus for warping or beaming yarns or threads.

454. L. A. Pouget, 39, Rue St. Sébastien, Paris, lamp manufacturer. Improvements in the manufacture of oil lamps.

456. J. J. Badart, 56, Bishopsgate-street. Improvements in the preparation of cotton seed cake.

458. N. Thompson, 15, Abbey-gardens, St. John's-wood. Improvements in apparatus for stopping bottles, jars, and other vessels, and in tools for producing parts of such apparatus.

Dated Feb. 20, 1863.

462. C. Billingsley, Manchester, saddler, Improvements in saddlery, harness, driving straps, and similar articles.

464. C. W. Siemens, 3, Great George-street, Westminster. Improvements in insulating and supporting telegraph line wires.

470. W. Husband, Hayle, and J. Quick, Sumner-street, Southwark, civil engineer. Improvements in apparatus for raising sewage and water.

Dated Feb. 21, 1863.

472. R. Thompson, Haigh Foundry, Wigan, engineer. Improvements in apparatus for moulding.

474. F. J. Manceaux, Paris, gun manufacturer. Improvements in firearms, or of transforming arms of large calibre into arms of smaller calibre.

476. R. V. Dodwell, Manchester, district engineer to the Magnetic Telegraph Company. An improved method of preventing the destruction of plants by insects and certain descriptions of animals, and in the means for effecting the same.

478. A. Crileur, Shawbury Villas, Camden-road, photo-lithographer. Improvements in apparatus for taking photographic impressions or likenesses by means of the camera.

480. H. Mackinder, Mere Hall, Lincoln. Improvements in apparatus for separating potatoes into different sizes.

482. A. Dugdale, Rue de Courcelles, Paris. Improvements in throttle valves.

Dated Feb. 23, 1863.

486. E. T. Hughes, 123, Chancery-lane. Improvements in the process of cleaning organic matter. (A communication.)

488. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in dressing millstones, in ornamenting or engraving on glass, pottery, and other similar substances, and in materials employed therein. (A communication.)

490. J. D. and A. P. Welch, Gutter-lane, straw hat manufacturers. Improvements in machinery for blocking and pressing hats and bonnets.

492. T. R. Harding, Leeds, hackle pin manufacturer. Improvements in carding and combing flax, wool, cotton, and other fibrous substances.

494. J. Tatham, Rochdale, machine maker. Improvements in machinery or apparatus for preparing cotton and other fibrous materials for spinning.

Dated Feb. 24, 1863.

500. J. Hawthorn, Burslem, china manufacturer. Certain improvements in handles for doors, drawers, and other means of enclosure.

504. J. Le-Butt, Bury St. Edmunds. Improvements in machinery for dressing grain.

506. D. B. Chatterton, Chester, mechanical engineer. Improved brick-making machinery.

508. H. B. Willson, Montague-place, Russell-square, barrister-at-law. Improvements in the construction of war and merchant ships.

510. A. Jünger, Hamburg, tailor. An improved life-preserving garment.

512. R. W. Thompson, Edinburgh, civil engineer. Improvements in obtaining and applying motive power; which improvements, or parts thereof, are applicable for raising, forcing, and measuring fluids.

514. W. Clark, 53, Chancery-lane, engineer. Improvements in sewing machines. (A communication.)

Dated Feb. 25, 1863.

516. H. Wilde, Manchester, engineer. Improvements in electro-magnetic telegraphs.

520. J. Fitter, Birmingham, machinist. An improvement or improvements in the construction of castors for tables, chairs, and other furniture or other articles.

522. E. B. Wilson, 5, Parliament-street, Westminster, civil engineer. An improvement or improvements in the manufacture of an alloy, or alloys, of titanium and iron.

524. B. Lawrence, Newport, Monmouth, architect, and W. Niblett, engineer. Improvements in apparatus for regulating the flow of gas for purposes of illumination.

530. W. Hudson, Burnley, gentleman, and C. Catlow, overlooker. Improvements in looms for weaving.

534. G. Tomkins, Morriston, Glamorgan, tin plate

worker. Improvements in the manufacture of tin and terne plates, and in the apparatus to be employed therein.

Dated Feb. 26, 1863.

536. W. H. Brown, Walham-green, gentleman. Improvements in window frames and in glazing windows.

538. G. H. Lilley, Dalston, draughtsman. Improvements in apparatus for connecting and securing together planks of wood applicable to the building and caulking of ships and other vessels.

542. J. Yates, Rotherham, iron master. Improvements in the manufacture of armour plates, or blocks, for defensive purposes.

544. W. Clark, 53, Chancery-lane, engineer. Improvements in the manufacture of buttons, and in apparatus for the same. (A communication.)

546. J. Humby, 14, Gresham House. Improvements in furnaces and apparatus for manufacturing oxide of zinc or zinc white. (A communication.)

548. F. H. Twilley, Dean-street, Soho. Improvements in book slides or holders.

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

From the *London Gazette*, March. 10, 1863.

2851. J. T. Stroud. Lamps.

2889. T. Pilgrim. Locks, bolts, latches, and other fastenings.

2893. G. Lindemann. Manufacture of bricks, tiles, slabs, and other articles of earthenware.

2896. J. Howie. Regulating the supply of solid or liquid bodies to mills or other apparatus used in mixing or preparing plastic matters.

2912. W. Clark. Ascertaining and recording the speed and distance travelled by vehicles, the flow and quantity of water, and other analgous purposes. (A communication.)

2916. W. E. Evans. Apparatus for playing organs, harmoniums, pianos, and other similar keyed instruments.

2996. C. Shield. Manufacture of malleable cast-iron.

2998. J. Petrie and J. Teal. Washing fibrous materials.

3006. H. Griffin. Securing india-rubber cylinders or rollers and blocks upon spindles and other bodies on which they are to be mounted.

3008. J. A. Fullarton. Painting or coating iron.

3016. H. Kilshaw and E. Lord. Power looms.

3021. E. Sonstadt. Manufacture of the metal magnesium.

3022. G. Kent and E. P. Griffiths. Reducing cocoa berries and other vegetable and animal substances to powder or pulp, and for mashing potatoes.

3027. J. B. Lavoine. Kitchen range.

3028. S. Berrisford and W. Ainsworth. Looms.

3032. W. E. Newton. Treatment of maize or Indian corn. (A communication.)

3034. T. G. Ghislin. Treatment of certain foreign plants.

3048. F. J. Clowes. Obtaining rotary motion.

2055. G. W. Rendel. Strengthening armour plates, iron or steel.

3067. E. B. Wilson. Conveying air, steam, gases, and fluids.

3090. C. Littleboy. Cultivating land.

3146. A. V. Newton. Machinery for cutting corks. (A communication.)

3150. W. Clark. Obtaining a vacuum or partial vacuum as applied in the manufacture of paper. (A communication.)

3251. R. D. Kay. Manufacture or finishing of endless machine blankets.

3358. J. J. Lemon. Book trays.

3416. E. R. Dann. Goffering apparatus.

113. J. B. Rock. Apparatus for saving life and property from fire.

173. W. Clark. Looms for weaving textile fabrics. (A communication.)

232. H. H. Henson. Fabrics for covering floors, walls, roofs, and other surfaces or objects.

257. J. H. Johnson. Manufacture of braid. (A communication.)

291. E. B. Wilson. Supplying air, gases, steam, or fluids to iron and other furnaces.

395. J. A. Schlumberger. Treating coal tar dead oils, and for producing phenic or carbolic acid. (A communication.)

447. F. J. Reed. Apparatus for traversing guns. (A communication.)

The full titles of the patents in the above list can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners' office particulars in writing of the objection to the application.

LIST OF SEALED PATENTS.

Sealed Feb. 24, 1863.

30. W. E. Newton.
2480. F. Selby.
2484. J. Saunders.
2485. J. Saunders.
2495. W. A. Munn.
2497. G. Weeks.
2500. J. Hemsley.
2501. R. A. Brooman.
2503. L. C. Hoyau.
2514. J. R. Johnson and J. S. Atkinson.
2518. A. J. Moreau.
2519. H. Higgins.
2520. G. Bedson.
2525. T. W. Cowan.
3562. J. W. Woodford.
2634. M. Henry.
2720. M. A. F. Mennons.
3336. J. W. Baker.

PATENTS ON WHICH THE STAMP DUTY OF £50 HAS BEEN PAID.

808. A. Pentzlin.
600. J. H. Johnson.
699. W. Weild.
602. T. W. Ashby and J. Coulson.
644. W. E. Newton.
880. W. Clark.
617. R. Pitt.
625. J. Imray and J. Copeland.
636. G. Spiller.
640. C. Sheldon.
650. J. H. Young.
776. J. M. Carter.

PATENTS ON WHICH THE STAMP DUTY OF £100 HAS BEEN PAID.

609. G. Rees.
893. A. V. Newton.
626. R. W. Winfield, J. Simms, and T. Lloyd.

IRON SHIPBUILDING BY CONTRACT.

In the drawn battle between the Controller of the Navy and the iron shipbuilders, there is in all probability truth on both sides, and the public are more likely to hear all that can be said against the Admiralty manifesto, than to be made aware of the complete state of the case against the contractors.

But, were we disposed to admit unreservedly the statements of Admiral Robinson with regard to the shortcomings of the private shipbuilders, we should be unable to justify the public attack upon them. The Admiralty has, or should have, the remedy in their own hands for any negligence or breaches of contract; and it is not satisfactory to know, that while they publish such grave charges against the contractors, their power of enforcing penalties has never once been exercised. Instead of punishing offenders, they have made large grants in favour of those who had distinguished themselves in a marked manner, by fulfilling their legal engagements.

It appears to us that the Admiralty system of granting contracts has very much to do with the failure of the builders to fulfil their engagements, and that it is fairly chargeable with part of the discredit.

A moment's reflection must have shown, even before they had the benefit of experience, that in such a matter as building an entirely novel description of ship, the construction of which would extend over two or three years, it would certainly become necessary to make alterations and additions which would invalidate any ordinary contract. Such alterations and additions have been made in every ship built for the Government. They were absolutely necessary; and to have allowed themselves to be deprived of such an advantage because of the breach of contract involved, would have been most unwise on the part of the Admiralty.

With this certainty before them, where was the use of a contract? It might have been so drawn up as to compel the builders to alter anything, and add everything which the Admiralty might think proper to order during the progress of the work, without any additional charge. We believe, in fact, that some of the contracts contained provisions amounting almost to this. But the contractors knew perfectly well that such absurd provisions would never be enforced; and they eagerly accepted the terms, regarding these extraordinary clauses as triumphs of official sagacity, which pleased the authors, and would not in any way hurt them. They knew that scores of breaches of contract, involving awful penalties, had been made during the Russian war, none of which had ever been enforced; and they knew, moreover, that according to official notions, the citation of a precedent was as good as an Order in Council. They therefore sent in low estimates, and excited the interest of their friends, for the purpose of securing the order to build on the Admiralty terms.

In the strength of their virtuous resolve to be uninfluenced by any party or personal considerations, their Lordships would be tempted to accept the lowest tender, although the firm tendering might be, by reason of insufficient capital and poverty of mechanical resources, most unfit to assume such responsibility, and conduct such vast operations. The consequence would be, as might have been anticipated, that many weeks and months would be consumed before the ground, plant, and materials were ready for the commencement of an undertaking, which although called by the same name, would be very unlike their ordinary operations.

No one inspecting the nature of the structures now growing into completeness in the dockyards on the Thames, from the Admiralty designs and under their supervision, can fail to perceive how different it is from ordinary iron boat building, both in the principle and in the manner of execution. "This is not," we are told by the foremen, "ship-building; it is engineering." The issue of the matter is, that, after vexatious delays from the want of preparation on the part of the contractors, of still further delays from the rejection of inferior material and workmanship on the part of the inspectors, the ship is complete. But the ship is known to have cost many thousands of pounds more than is due under the contract. Enforcement of penalties is out of the question; and it only remains to be settled how much shall be allowed for extras, and towards the reimbursement of the contractor. In such a case it is clear, that it would have been far better to have given the order to build the ship to some well-established and trustworthy firm, and to have arranged for payment upon some equitable principle, without imposing the fetters of a contract upon either party.

Although much may be said in favour of employing wood just now in the construction of iron-cased ships, the day is rapidly approaching when ships of all descriptions will be constructed of iron; but before that can come about, several difficulties will have to be removed. That they exist, no one can deny; that they are capable of removal, we cannot doubt. Under those circumstances, it will probably be desirable to build most, if not all, our ships of war in private establishments, and it will be necessary to consider whether such a course as that which we have indicated would not be more desirable than the continuance of the present system of contracts.

Some of the private builders are very indignant at the charge made against them in this document, that their work is often performed in a slovenly manner. They wish us to believe that, whatever amount of slovenly workmanship, and bad material, found their way into the wooden vessels built under contract for the Government, nothing of the kind is tolerated in the iron establishments. Having our suspicions on this matter, we turned to the recent volume of the "Transactions of the Institution of Naval Architects," which we have had under review during the last two or three weeks, and we find evidence, from an impartial witness, bearing directly on the point. In a Paper read by Mr. Grantham, the author of a very valuable work on Iron Shipbuilding, we are told that in a former Paper he had attempted to show that, "as regards *the distribution of the materials* in iron shipbuilding, the proportions which generally obtain are anything but satisfactory.

"As regards the *quality of the materials* used, I think it is generally agreed that it ranges from a strength represented by about 15 up to 35; 15 being a denomination for common boat plates, and 35 the improved iron called puddled steel, of which many vessels have been built. If it were possible to test the range over which the extremes of *bad and good workmanship* in the matter of jointing and rivetting extend, it is probable we should find it to be equal to either of the two former questions. I cannot, however, offer any direct proofs of the extent of this range. I can only assert that it is very wide; and I trust, in the course of my remarks, to throw out some suggestions that will tend not only to reduce it, but to ensure for those who take proper means to protect themselves, more reliable methods for obtaining sound vessels.

"The present system of jointing and rivetting iron ships may be compared to the mode of jointing machinery as it existed upwards of twenty years ago. No attempt was then made to fit the joints, but space was left for cement to be caulked into them: the bolt holes were also cast in the flanges, and made fair by chipping. This system in all good work is exploded: the joints are planed and no cement is needed: the holes for the bolts are drilled, and are an exact fit: the work is tight: the strength is much increased: and the weight of iron in the flanges reduced in proportion.

"In iron shipbuilding the ordinary system is to fit the joints by rude means, bringing them as close as is thought necessary, and by the caulking tool to do the rest, which in many cases amounts to nothing more than the concealment of defects. The holes also are punched as nearly opposite each other as is considered necessary and practicable, and a drift is supposed to set all right."

As regards butt joints, he goes on to say, it is notorious that in no place do iron ships sooner show weakness than in these, and in no part of iron shipbuilding is the system so deficient.

The method adopted in plating is, he tells us, to attach the plates to the frames of the ship in regular shear lines, commencing from the keel, if the vessel has one, and sometimes simultaneously at the shear strake, applying first those strakes that lie close, without lining pieces, to the frames. These plates being previously punched are brought together at the butts, and temporarily secured by bolts and nuts. To make the ends a tolerable fit, a hammer is generally used, knocking down the higher parts and throwing up a burr on one edge; but as this operation is very imperfect, the plates in reality only touch at points, and even in what appears to the eye a good joint, the plates often only touch at two or three points, perhaps for a quarter of an inch, or some very short length. In other cases, where still less care is observed, the joints will touch at one corner of the plates only, and be entirely separated from all the rest. These defects are quite visible at first, but when the butt plate is put on the light can no longer be seen through the joints, and thus observation is partially prevented. When the men are told of it, the reply is that the rivetting will stretch the plates and close the joint; but though this cannot be relied upon to any extent to compensate for the width too frequently left, yet all questions are set at rest by the caulking tool—a flat chisel which is passed over the joint—knocking down the burr which has before been raised, and closing the plates at the upper part of the joint. This system makes the joint *water-tight*, but is so evidently defective in strength that no one ought to be satisfied with it. All parts not really in contact, however slight the separation may appear, are deprived of the great additional strength which well butted plates must afford.

And, with regard to rivetting, he tell us that, as a rule, the holes in the plates through which the rivets are to go are never fair with each other. Under these circumstances, he says, "if the rivet be very hot, and the hole not very irregular, by dint of hard blows the hole is well filled and the work sound, though about this there is no certainty. But suppose the hole is very much distorted, the countersink half destroyed, and an abrupt angle at the centre caused by one plate partly overlapping the hole of the other, the effect" then is, that the holes "are not filled, and the rivet, when severely tested, becomes loose. There are, of course, all degrees of distortion; some so great that the head of the rivet will scarcely conceal the vacancy." "It is evident that wherever this vacancy occurs, however small it may be, the efficiency of the rivet is greatly reduced; and, supposing further (a case which occurs every day in our best ships), that in the same seam both the rivets and joints have the defects above described, how greatly must the general strength of the ship be diminished!"

In the face of such evidence as this, the virtuous indignation of our iron shipbuilders is rather out of place, and we must leave them with the hope that, before we are compelled to trust our fleets to their tender mercies, they will have been able to remove the causes of complaint on which the Controller of the Navy bases his case against them.

THE FIVE NEW IRON-CLADS.

THE division on Mr. Lindsay's motion, and the arguments which influenced the majority, disclose a melancholy picture of the corruption which pervades the administration of public affairs in this aristocratically governed country. A plain question of fact, affecting the most vital branch of national defence, and involving the expenditure of a million, is distorted and literally strangled by a combination of Ministerial misrepresentation and political juggling, which never have been surpassed. The Navy Estimates comprise a sum for the construction of five iron-clad men-of-war. The Government proves, to the satisfaction of the House of Commons, that this increase to our line-of-battle is imperatively called for All parties are agreed on that point. Liberals and Conservatives, patriots and economists, even the peace party, admit the necessity of the vote.

There is, however, a subsidiary question, on the vast importance of which all parties are equally unanimous, for upon it depends the honour and safety of the nation. Shall these five iron-clads be iron or wooden vessels? "From some defects in ships of war," says Lord Palmerston, "a battle may be lost, and no man can tell the disastrous results to a country of the loss of a naval engagement." This appeal to the good sense and patriotism of the House elicits cheers, and it is founded on truth; but, as we will presently show, the words are mere clap-trap in the mouth of the Premier. They are uttered to persuade members to support a measure, which, at the supreme moment, will immensely diminish the chance of victory to a British fleet.

The universal opinion of the House is in favour of iron ships. Admiral Robinson, in his statement, which may be taken as embodying the conclusions of the Board of Admiralty, says that an iron ship can be built of larger dimensions, has more rigidity and strength of structure as a whole, and has much greater durability than a wooden ship. Some imperfections in iron ships, especially local weakness of the bottom, and liability to foul, are mentioned; but these points are fully and fairly discussed by members without distinction of party, and the general assent is given to the conclusion that, after all, the defects referred to are of secondary importance. For the reason assigned in Admiral Robinson's statement, they are outweighed by the immense superiority of iron as the material for ships of war. But what means this discussion at the present day? What consummate hypocrisy it is on the part of Government, to question the superiority of iron over wooden armour-plated ships, when for the last twelve months they have never ceased describing the admirable qualities of the "Warrior," holding her up as the finest iron-clad in the world, because *she is built of iron*, whilst they insisted on the inferiority of the "La Gloire" and other French iron-clads, because *they are built of wood*.

Are the English people to be stultified in this way? Is a vote on a great national question to be carried in favour of Ministers and against common sense, because the "jaunty Premier," regardless of consistency, gives utterance to a patriotic sentiment, founded on misrepresentation. Those members of the deluded majority, whose votes were thus juggled out of them, must wince and feel ashamed, when they reflect that they are answerable for authorizing the Admiralty to build five ships-of-war of a material, deficient in strength and rigidity, which they know is the source of the defects by which a battle may be lost.

As Lord Palmerston has rightly placed the issue, in this grave question, on a possible naval defeat if we build defective iron-clads, let there be no tergiversation on that point. Is the "Warrior" as a war frigate superior in strength, speed, and sea-going properties, to the "La Gloire," and other French iron-clads; and is that superiority due to the former being an iron and the latter a wooden ship? If these be facts, why is the country to be tricked into the expenditure of a million, to add to its navy five men-of-war of the inferior and defective class, instead of five of the superior and effective class? If they be not facts, then has the country been shamefully imposed upon, by the reports ostentatiously published of the wonderful perfection of the "Warriors," "Minotaurs," and "Achilles," for which three or four millions were freely voted on the faith of those reports.

Whether the facts on one side or the other be true or not, there is but one inference to explain the course now taken by Ministers. The false position in which they place themselves by assuming the resposibility of building five men-of-war, arises from the jobbery which is the vice of Admiralty administration.

Wood is the life of the dockyards. The officials, from the Controller, through all the grades of the constructive department, to the shipwrights, masters and men, the favoured clique of contractors for timber, and their hangers-on—every individual of this large body has an interest in wooden, and none in iron, vessels, because the former can, and the latter cannot be built in the dockyards. The united influence of all their interest weighs so heavily on the Government, that Ministers are compelled to come down to the House and make out a case for wood against iron. The attempt is a bold one. It required all the cool effrontery and parliamentary skill of the Premier to undertake it. So far the plot promises success; but will it be carried through? Notwithstanding the large majority, perhaps not!

We will analyze the means by which votes have been caught, and by opening the eyes of honest members of the the majority to the deception practised upon them, we may succeed in turning their votes to the side of reason, truth, and patriotism, when the question again comes before the House.

Fortunately, there is a hope of salvation. To induce the House to leave to Ministers the responsibility of building five ships of wood or iron at their discretion, and not to tie the hands of the executive, Lord Palmerston was obliged to commit his Government to the promise, that the Admiralty will make experiments to ascertain which class of vessels "may be best suited to the wants of the country."

This is a specific pledge, to which the House of Commons, when it has recovered its senses, will keep the Premier fast bound. He cannot escape from it. He has already announced one course the Admiralty intends to follow. "In the course of this summer, there will be a mode of testing by experiment the qualities of the 'Royal Oak,' a ship of wood, but strengthened with an iron coating, as compared with those of the 'Hector,' a ship of the same size but built entirely of iron, and the result of that experiment, will instruct the Admiralty as to the course to be pursued with respect to the number of ships necessary to be built." So far, so good; but let it be the business of those independent members who understand this question, and have so ably defended the cause of iron, to keep their eyes upon the 'Royal Oak' and exact from Government the execution of the bond before any of the money voted for the five iron-clads be invested in wooden frames. If they do not, they may be assured that the manœuvre exposed by Mr. Cobden will be repeated. As the dockyard people, without the knowledge, it was stated, of the Board, first laid in an immense stock of wood, and then made that stock an argument for building wooden ships, so will the same official worshippers of wood, if not looked after, speedily convert timber into frames, and then will innocently urge that, on the score of economy, these frames must be converted into iron-clads, otherwise the money they have cost will be lost to the country.

But to fulfil the Premier's pledge, there remains another course, more important to the country than that determined upon by the Admiralty. A trial cruise of the "Royal Oak" in search of gales of wind may test her sea-going properties, and show how she carries her heavy weight of armour and armament; but the severest trials at sea will tell us nothing about her powers of resistance as an "iron-clad." They will not enlighten us as to whether her armour plates and teak backing on a wooden hull may not be more easily penetrated than the same armour on an iron hull. But "that is the question," and a question which must be solved positively and unequivocally before Parliament allows another shilling to be spent on wooden hulls or frames. Let Lord Palmerston's prophetic words be remembered! Defects in the construction of a man-of-war may lose a battle and imperil the safety of the country. What greater defect can there be than inferiority of resistance to the enemy's guns?

There is an easy mode of setting this question at rest—one so inexpensive that, after the debate last week, after the pledge extorted from the Minister, the House will not be true to itself or to the country if it do not exact the adoption of the mode we allude to which is to have a "Royal Oak" target constructed and fired at at Shoeburyness. If this be done, the country will know the value of an armour-plated wooden broadside. If it be not done, the country will have reason to be dissatisfied. To this extent Parliament may, without compromising itself, take the responsibility of dictating to the executive. This target should be of the same dimensions as the "Warrior" section, which we heard so much about. The expense will be about £2,000. If the House demand the expenditure of so small a sum for so good a purpose, they cannot be warned that it is unconstitutional to increase the expenditure beyond the Estimates. A handsome sum is set down for Admiralty experiments. Before that item is voted, let it be an instruction to the executive that a sufficient sum be appropriated, without delay, to construct a "Royal Oak" section and that it undergo the same series of experiments under the fire of great guns as the "Warrior" section was subjected to.

When the question is before the House, it would be wise, at the same time, to demand the construction of a similar trial target, representing a section of the armour-plated broadside of the "Enterprise," of which the force of resistance to artillery ought to be tested before Mr. Reed's invention is carried any further. We make no doubt more than one member will be prepared to move a resolution comprising this double proposition; and if it is moved, we are sure Ministers will not venture to oppose it, or if they do, they will be defeated by a large majority.

MACHINERY BELTING.

There is no simpler, or smoother means of communicating motion than that afforded by the noiseless agency of cords, bands, or straps. The very means by which the motion is maintained, namely, by the frictional adhesion between the surfaces of the belt and the pulley, is a safeguard to the whole mechanism; as if any unusual or accidental obstruction should intervene, the belt merely slips, and breakage and accident is thus prevented. When, however, the motion is required to be conveyed in an *exact* ratio, belts are inapplicable, from their tendency to slip. Slipping may, no doubt, be prevented by various means; but it will be shown in the following interesting investigation that, even where the precise action known under the name of slipping does not occur, there is, nevertheless, a certain amount of inaccuracy in the transmission of the speed.

We have extracted the following from the first number of "Annales des Mines," of last year:—

It is generally admitted that in any transmission of movement by means of belts, the speed of the driving shaft is communicated to the shaft driven, at a velocity inversely as the respective diameters of the pullies; of course, supposing that the belt has sufficient initial tension to prevent any slipping.

We shall endeavour to prove that a rigorously exact communication of speed can scarcely ever take place, and that the shaft driven always revolves somewhat slower; and, further, that this diminution of speed is often sufficiently great to require an allowance in calculating the diameters of a set of pullies.

If we suppose a pulley A, communicating motion by means of a belt to a pulley B, fixed on a shaft parallel to that of the pulley A; let R be the radius, and w the angular velocity of the pulley A; and further, R^1 the radius, and w_1 the angular velocity of the pulley B. We will now suppose that a force F is acting at a tangent to the pulley B, and in a contrary direction to the motion.

In order that a uniform movement should take place, the driving portion of the belt must take a tension T, and the strap that is lead a tension t, while the difference of these two tensions $T - t$ must be equal to F. But the belt is made of an elastic substance, continually changing from one tension to another, and thus altering its length, so that if we fix upon any two points of the belt in motion, the distances between these two points will vary with the tension the part under consideration is undergoing. Whatever be the general law of the variation of tension of the strap at the different points, it is evident that the movement of this belt has all the character of *permanent* motion, and that, in consequence, the quantity of matter passing over the different points in the same time is the same; it is necessary, to produce this effect, that the *natural length* of the strap passing at the different points during the same time be constant. We understand by *natural length* of a part of a belt submitted to a certain tension, the length that such a portion of the belt would have if there were no tension. If we call l the *geometrical length* of the belt, at a tension t, rolling itself within a time O, over the pulley B, a *geometrical length*, l^1 of belt at a tension T will unroll itself during the same time, and this length will be such that its *natural length* will be the same as that corresponding to the lapped round part t. It is thus clear that, contrary to the common belief, the *geometrical length* of the part of the belt rolling itself round the pulley during a time O, is less than the geometrical length that unrolls itself during the same time, and, as a consequence, that there is necessarily a slip on the pulley in the direction of the motion.

It will also be seen that the geometrical length of the belt lapped round in the time O, by the pulley A, is larger than the geometrical length that unrolls itself during the same time, and there is, consequently, a slip of the belt in a contrary direction to the motion.

If we express the equality of the *natural lengths* of belting lapped round during a time O by the pullies A and B, we shall have, represented by *a*, the stretching of the unity of length of the belt under the influence of the unity of tension:—

$$\frac{R\,w\,O}{1 + a\,T} = \frac{R^1\,w^1\,O}{1 + a\,t}$$

from which

$$\frac{w^1}{w} = \frac{1 + a\,t}{1 + a\,T} \cdot \frac{R}{R^1}$$

We thus see that the ratio of the speeds is equal to the inverse ratio of the radii multiplied by a co-efficient, that is only equal to unity when these two tensions are equal—that is to say, in case there is no work to be transmitted, or in case the initial tensions of the belt be infinitely great. The speed is thus always more or less diminished, and the means generally adopted—namely, to tighten the belt, and thus increase the initial tension—is a more injurious than useful remedy, as it increases the passive resistances to the transmission of motion. It is easy to determine the average amount of this co-efficient of the diminution of speed. The writer recently made a series of experiments to determine the value of *a*. He found, taking for unity of length the metre, and for unity of tension the kilogramme, that

$$a = \frac{0{\cdot}16^{\text{m.}}}{S}$$

for belts of common leather that had been in use for some time; and

$$a = \frac{0{\cdot}21^{\text{m.}}}{S}$$

for new belts, S representing the section of the belt in square millimetres.

In practice it is generally admitted that a leather belt carries ¼ kilogramme per square millimetre in section, that is to say, that $S = 4\,T$; we would thus have

$$a\,T = \frac{0{\cdot}16}{4}$$

for belts that have been in use for some time, and

$$a\,T = \frac{0{\cdot}21}{4}$$

for new belts.

As to $a\,t$, it is equal to

$$a\,T \times \frac{t}{T}.$$

We can have an approximate value of $\frac{t}{T}$; in fact the strengths of belts are always calculated in such wise that they can resist the tension required to prevent a complete slipping on the drum. We are not now referring to the slipping caused forcibly on the drum by the lengthening of the strap, but of a slipping produced simultaneously in the whole part of the strap rolled on the drum, and resulting in a cessation of motion to the pulley driven. It is generally demonstrated that, to render this complete slipping impossible, we must have (tension) $T < t\,e^{fb}$, f being the co-efficient of friction of the belt on the drum, and b the ratio of the arc of the pulley embraced by the strap to the radius of the pulley. In practice T is generally made $= 0{\cdot}9.\ t\,e^{fb}$, a ratio that, in the case of a leather strap embracing a cast-iron pulley, becomes $T = 2{\cdot}16\ t$. Not to exaggerate the importance of the diminution of speed, we will take $T = 2\,t$, from which

$$a\,t = \frac{a\,T}{2}.$$

We can easily find that the average value of the co-efficient

$$\frac{1 + a\,t}{1 + a\,T}$$

will be—for belts that have been used,

$$\frac{1{\cdot}0225}{1{\cdot}045} = 0{\cdot}978;$$

for new belts,

$$\frac{1{\cdot}0262}{1{\cdot}0525} = 0{\cdot}975.$$

We thus see that the diminution of velocity is about two revolutions for each hundred; this would have but a slight effect on a pair of pulleys; but it is often necessary to use a train of pulleys, and we thus often get very great differences between the real and calculated velocities. It is seen at once that if the coefficient of the diminution of velocity is 0·98 for a single pair of pulleys, it will become, in many cases, equal to the successive powers of 0·98, which are 0.98....0·96....0·94....0·92....0·90, nearly; so that, after a succession of 5 speeds, the loss of velocity is already the tenth of the calculated speed, and that at the end of about 34 speeds, the velocity will be reduced to one half.

The writer has made a great number of experiments to verify these results, and he has determined that, in all cases where the dimensions of the belts do not much depart from those indicated by the calculation, we generally find an average of 0·98 as a coefficient. The formula has also been verified with great certainty by varying the tensions of the same belt. To produce this effect, the writer employed, instead of a leather belt, a band of vulcanized india rubber, a substance in which *a* is pretty nearly equal to $\frac{S}{1}$, by by which it is possible to acquire a very considerable diminution of speed. This band was placed on two pulleys of equal diameter; a small friction break on one of the shafts allowed the resistances to be altered. A series of equal divisions marked on the band permitted the tension to be estimated during the motion. The results were perfectly in accordance with the formula.

From all these considerations it appears that, where it is required to transmit determinate speeds by means of bands and pulleys, it is prudent to increase by about 1-50th the diameter of the driving pulley, or to diminish the diameter of the following pulleys, in the same ratio.

When the power to be transmitted from a prime mover exceeds a certain limit, it is necessary to employ flat belts or straps, working on pulleys, with rims made slightly convex, in a ratio of half an inch per foot of breadth. When the power to be communicated is less than that of two men, cords working in pulleys with round or angular grooves are preferable. Beyond this power, a flat belt may be employed, and when certain limits of power and velocity are exceeded, straps must generally make room for toothed wheels. It is well known that long belts give a much better effect than short belts.

Small flat straps are sometimes used instead of hempen or gut cords for smaller machines; this practice, however, is not in general acceptance. A cord is more easily pieced together than a small narrow strap. A leather strap however, is more elastic than a cord, and is also less hygrometrical or subject to stretch in wet weather. It is important not to stretch too much belts and straps, as there is otherwise much power lost in producing a given effect. It is generally reckoned that from 1 to 2.2 per cent. of the power communicated is lost by the stiffness of a leather belt. An interesting investigation into this matter will be found, 5 Heft of the "Schweitzer Polytechnischen Zeitschrift" for 1861.

In our volume for 1825, p. 69, will be found a valuable letter from Mr. B. Bevan, giving an account of some experiments to ascertain the strength of leather. The practical table this correspondent gives is the following:—

	Cohesion—lbs. per sq. inch.	Modulus of Cohesion in feet.	Ratio of Extension by half breaking weight.
Calves skin	1,890	5,050	0·165
Sheep skin (basil) ...	1,610	5,600	0·191
Horse skin (white) ...	4,000	11,000	0·187
Horse skin (Russ) ...	3,200	7,000	—
Horse skin (Cordovan)	1,680	3,720	—
Cow skin	3,981	10,049	0·22

The "modulus of cohesion" is the length in feet of leather required to break its own cohesion, or tear it asunder.

Rule.—To find the weight necessary to break or tear asunder any strip of leather, it is only necessary to ascertain the weight of one foot in length in lbs. and decimals, and multiply the modulus in feet by the weight so found; the product will be the greatest load the strap will bear, even when the leather is new; but not more than one-third or one-fourth of the weight thus found should be trusted for any considerable time.

The following are some neat formulæ appearing in "Molesworth's Pocket-book of Engineering Formulæ." They are for ordinary leather belting used in common cases, at not very high speeds:—

V = velocity of belt, in feet per minute.

H P = horse-power (actual) transmitted by belt.

$$x = \frac{33000 \text{ H P}}{\text{V}}$$

S = strain on belting, in lbs.

W = width of single belting (3-16th thick) in inches.

$$\text{S} = x + \frac{x}{k}$$

$$\text{W} = \frac{\text{S}}{50}$$

k = ·09 when portion of driven pulley embraced by belt = 0·40 circumference.

k = 1·3 when portion of driven pulley embraced by belt = 0·50 circumference.

k = 1·6 when portion of driven pulley embraced by belt = 0·60 circumference.

For double-belting the width = W × 0·6.

Approximate rule for single-belting 3-16th thick.

$$\text{W} = \frac{1100 \text{ H P}}{\text{V.}}$$

An empirical rule for ascertaining the width of pulley straps that we know to be in use by some good practical men, is as follows:—

$$\text{B} = \frac{31{\cdot}4 \text{ N}}{n\,d}$$

in which formula, B is the width of strap required (the thickness of the leather being taken at 3-16th); N is the number of horse-power; n is the number of revolutions; and d is the diameter of the pulley.

The most generally used mode of connecting the ends of leather straps is by means of laces or thongs of leather. Other methods have been tried, such as glueing the ends together, or using hooks or clasps. Rivets, studs, and screws have, to some extent, been employed. Pegs have also been proposed (*Vide* Patent No. 3163, 1860).

The following is a *recipe* for a composition or glue that will stick the ends of belts together. We believe that it has been tolerably successful, and it is said to have stood 4-horse power when carefully made, and similarly applied. Take:—

8 parts of the best glue,
4 parts of isinglass,
2 parts of gum arabic.

The glue must be boiled down, and stirred up till it assumes a tough, thick consistency. Then pour in three-fourths of spirits of wine, and let it dissolve the mass. The isinglass, previously dissolved in warm water, is now mixed with the above and stirred up together. Last of all, the gum arabic, dissolved in water, is poured on, the whole carefully mixed together, and the composition is then fit for use.

As might be expected, from the fact of an article being so greatly in demand as leather belting, there are large quantities of cuttings and waste annually evolved from the manufacturer of these useful mechanical organs. Most inventors who have found the means to utilize what was previously refuse, have deservedly accumulated large fortunes. Accordingly, in France and America, attempts, more or less successful, have been made to utilize the waste cuttings of the manufacturers of leather articles. We believe that at Abington, in the State of Massachussets, there is a steam engine of about 8-horse power, solely employed in grinding and pulverizing the waste cuttings usually thrown away or burnt by saddlers, shoemakers, &c. The waste pieces are reduced to powder, and are then mixed with vegetable gums and other substances, by which means the whole obtains such cohesive power that the mass becomes a kind of soluble leather. In a short time the composition acquires sufficient consistency to allow itself to be passed through rollers, and thus to be brought to the required thickness.

Other and more direct means have been attempted to utilize small waste pieces of good leather. Monsieur Roullier, of Paris, himself a manufacturer of artificial leather, has made certain peculiar belts of waste leather cuttings, and some were exhibited at work in the Western Annexe of the International Exhibition. We described his plan in our number for September 19th, 1862.

These "courroies en cuir articules," as they are called by the French inventor, consist of a number of small flat links of 3-16th leather united by long pins of the breadth of the band. The pins have heads, and are rivetted or clenched back on a washer at the other end. In a 3-in. broad specimen of this description of belting, the pins are about ⅛ of an inch in diameter, and about half an inch from centre to centre. The belt working in the French part of the Western Annexe appeared to stand the strain very well. The links of leather are stamped out and the holes punched in by a machine, and they are threaded on to the pins by workwomen. Mons. Roullier is said to have an establishment in Paris employing three hundred workmen, and he can deliver one hundred metres per day of his peculiar belting. He has recently used small links of zinc between those of leather. It appears to us that an objection will be found in this belting from the fact that there is necessarily a tendency in the joint-pins to bend to the curve of the pulley, and a continuation of this action would naturally lead to the breakage of the joint-pins.

A very remarkable and important description of belting, the invention of Mr. William Clissold, of Dudbridge, Gloucester, was exhibited at work in the Belgium Department of the Western Annexe of the International Exhibition. These bevel-edged belts were first patented in 1860, May 22nd; but not being found sufficiently strong, the *continuous* bevel-edged belts were altered into a kind of chain of separate links. The wedge-shaped links are made of strips of leather coiled up to the ordinary figure of a link, and these links are connected together by link plates carrying a stud at either end, which studs enter the adjacent links and hold them together. This description of belt, or rather chain, has acquired great importance from its being used by Mr. John Fowler to communicate the motion of an ordinary portable engine to the moveable clip drum in front; by which means the ordinary portable engine can be used in ploughing upon the "direct acting" system. We also saw some small bands entirely of cotton, at Messrs. Apperley and Clissold's stand in the Western Annexe.

An ingenious and efficient leather belt is manufactured by Messrs. Bryant and Cogan, Broadmead, Bristol, according to the patent of Mr. Haines (No. 406, 1860). These bands are built up of narrow leather strips or fillets, each piece being of the thickness of the intended driving strap, and they are placed side by side with the cut edges of the leather placed outside. The straps are made to break joint, and holes are bored through them at intervals from edge to edge of the strap, and the straps are then fastened together by pieces of wire. It will thus be seen that a description of band like this may be made of any length or thickness, without laps, cross-joints, &c. These bands may also be used much slacker than the common strap, as the rough surface ensures a greater amount of adhesion. The band is made a little shorter than the required length, in order that two iron shackles may be kept a few inches apart. As the band stretches, the shackles may be gradually drawn closer, by means of wide laces, until they meet: should the band afterwards stretch, one of the shackles may be set further back by filing off the bur at the end of the pin, cutting back the leather, and inserting the pin through the shackle into the next hole. One of these patent bands was exhibited at work in the Belgium Department of the International Exhibition.

There were several machines in the Western Annexe of the International Exhibition driven by a description of leather belt manufactured by Messrs. Sampson, of Stroud. From its peculiar make no cross joint was required in a length under 200 ft. It was formed of two narrow strips of thick leather, and three narrow slips were sewn on at the back.

There was a slip sewn to each edge, and an additional third strip at the joint in the middle. We have heard practical men say that this belt gave remarkably good results.

We also noticed some excellent double leather bands in the North-East Court of the Eastern Annexe of the International Exhibition. They were exhibited by Webb and Son, of Stowmarket. One of the double bands exhibited was 14 in. in breadth. There were also some edged and single belts. Several patents have also been recently taken out for improvements in treating hides and skins for machinery belting.

Many engineers probably still think that "there is nothing like leather" for straps. Nevertheless, those remarkable vegetable gums, caoutchouc and gutta percha, have been employed in various ways, and with great success, in the manufacture of belting. A large number of these belts were at work in the Western Annexe of the International Exhibition. It is to be regretted that the many extensive manufacturers of these important mechanical agents have not instituted a series of careful experiments giving the breaking strain, coefficient of friction, loss by stiffness, &c., of india rubber and gutta percha belts, as compared with those of leather.

Most of the india-rubber belting sold seems to be very similar in appearance; but the processes of manufacture probably differ. Mr. S. T. Parmelie, of Edinburgh, patented in 1858 (No. 777) certain machinery and a peculiar process for manufacturing belting. The belting is made of several layers of woven material, cut into strips of the width required. The whole is then passed between the peripheries of two rolling cylinders united by an endless metallic band, in such a manner as to admit of the belting being passed between one of the cylinders enclosed within a headed chamber and the endless metallic band. The cylinders are provided with one or more grooves corresponding to the required width of the belting. These bands, which are said to give good results, are manufactured by the North British Rubber Company, Castle Mills, Edinburgh. The woven material that affords the basis for the india-rubber, is said to be made of Sea Island cotton. The material is claimed to be superior to leather for damp places, and to gutta percha in situations subject to variations of temperature. The bands are joined together with laces, or by an india-rubber lap and screws.

The well-known firms of Warne and Co., Gresham-street, Macintosh and Co., of Manchester, Hancock, Goswell-mews, and Moses, Son, and Davis, Cheapside, are all manufacturers of india-rubber belting, so that it will be seen what an important demand already exists for this description of band.

The belting manufactured by Messrs. Spill, of Stepney-green, according to patent No. 2550, date 1859, consists of a band of steel wire, covered with several strands of hempen cord, previously passed through a solution of either india-rubber, gutta percha, glue, or drying oils, &c. After the strands have been applied the whole is carried through rollers. Any number of these smaller bands are then placed as warps in a loom, and similar materials to those covering the steel bands are then used as the weft, so that the whole is woven together. The band is afterwards again passed through rollers, and (either before or after this operation) it is coated with caoutchouc. This invention is also remarkably ingenious.

We have heard some good accounts of the gutta percha bands manufactured by the company of the same name, of City-road, in the metropolis. They are largely used by Truman, Hanbury, Buxton, and Co., as some of the advantages of these bands consist in their non-susceptibility of injury from greasy or chemical substances, and the ease with which the joint may be made. The following are the directions given by the manufacturers for making the joints:—

"Cut the ends of the band obliquely at an angle 30 or 40 degrees, making the band rather shorter than the length required. Secure one end to a board or bench by a clamp or a couple of nails. Having heated a piece of iron (say one inch broad and half an inch thick) to the temperature of a laundress's smoothing iron, so that it will soften the gutta percha without burning or discolouring it, place the iron between the cut edges of the band, pressing them against it (keeping the band always in a straight direction) until the edges are thoroughly softened, and in a sticky state; then remove the iron and press the two edges together as closely as possible, after which a couple of nails may be driven into the loose end of the band, to keep it in its place. The ridge or burr may be pressed down as much as possible into the substance of the band, by a heavy weight or by means of a clamp, so as to make a smooth joint. A band of ordinary thickness will be ready for use in ten or fifteen minutes, or sooner if cold water be applied. Flat joints may be made in like manner, by shaving down the ends a little (so as, when laid one on the other, not to be much thicker than the band), heating the surface of the splices, and pressing them together by a weight or clamp. Avoid heating the band throughout. Pare the edges when cold." Cross bands made of gutta percha must be separated by a roller, or a fixed round iron bar, if there be much friction or rapid motion.

The West Ham Gutta Percha Company are also manufacturers of similar bands.

An interesting description of belting was exhibited in the American department of the International Exhibition. It was made chiefly of wool, and the surface of the belt was covered with a resinous cement. We saw a small piece that had been in use for two years and a half on a heavy cloth loom in the States. We believe that some belting of this material is working some looms in the Mills of Smith, Brothers, and Co., of Heywood, Lancashire.

II.

ENGINEERING LITERATURE.

The author of an excellent and well-known work on bridges, Mr. William Humber, Assoc.Inst.C.E., and Memb.Inst.M.E., is now editing a new engineering monthly serial.[*] The two numbers we have seen, for the months of February and March respectively, contain an account, fully illustrated with steel engravings, of the roof of the Victoria station of the London, Brighton, and South Coast Railways. We consider that a greater number of dimensions might have been given on the detail drawings, as also more centre lines. Centre lines do not increase the beauty of a mechanical drawing, but they add considerably to its intelligibility and usefulness. The Editor proposes to give illustrated descriptions, as the work proceeds, of the London, Chatham, and Dover, and Great Western railways; the Charing-cross railway station, with full detail drawings of the roofs; also the roof of the Amsterdam station of the Dutch Rhenish railway; the Metropolitan Railway; the High Level Sewer, &c., &c.

The points of contact between practical engineering and chemistry are so numerous that an engineer can scarcely practise with any success without some knowledge of chemistry. More especially by those whose education dates from the "pre-scientific era" would a good chemical encyclopædia be a great boon. This is attempted to be furnished in a work of which we have seen the first part; written by the editor of "The Journal of the Chemical Society."[*] We understand that the work was originally intended to be issued as an edition of Ure's well-known "Dictionary of Chemistry and Mineralogy," but the great progress made in physical and chemical sciences since the date of the last edition of that work (1831) has required a complete refounding of the book. The Editor has freely availed himself of the works of the German *savants*: the best chemists in the world. In order to render the work more generally intelligible, the formulæ of the older or dualistic system are also given, and are printed in *italics*. The centigrade scale is also used.

We always hail with satisfaction the appearance of a practical engineer in the literary arena. From various causes, engineers are so chary of writing, or even of compiling, that invaluable records of the life-experience of many able men have been often lost to the profession. The principal assistant engineer of the Ceylon Railway, Mr. G. L. Molesworth, has lately published an excellent and compendious Vade-mecum for the use of engineers.[†] The usual so-called "Engineers' Pocket Books" require rather a carpet-bag than a pocket to carry them about, while at the same time they discuss subjects with too little amplitude for a leisurely reference. This small book only measures 5 × 3¼ × ½, and yet contains 220 pages, besides some blank leaves; the whole closed by an elastic band. Perhaps it would have been better if the blank leaves had been distributed through the work, so that each possessor could note down additional formulæ to those in the book; as it is impossible to expect that such a small work could meet every special case. This small Vade-mecum is divided into three parts, touching on nearly 500 subjects connected—1, with Civil Engineering; 2, Mechanical Engineering; 3, An Appendix. The part on Civil Engineering contains 62 pages, and gives the formulæ applicable to surveying, earthwork, beams, roofs, railways (12 pages), waterworks, warming, &c. &c. That on Mechanical Engineering consists of 84 pages, and as per synopsis it touches on gravity, mechanical centres and powers, millwork, teeth of wheels, shafting, belting, alloys, solders, and workshop recipes (very good), steam boilers and steam engines, waterwheels, turbines, &c., windmills, paddle and screw steamers, and miscellaneous machinery. The Appendix gives the usual aids to calculation, such as weights and measures, English and foreign, logarithms, trigonometrical formulæ, squares, cubes, powers, roots, and reciprocals, &c.

II.

CARRIAGEWAYS AND FOOTPATHS.

Sir John Scott Lillie, Knight and Companion of the Military Order of the Bath, of 105, Pall-mall, has lately taken out a patent for the construction of carriageways and footways.

These improvements consist in the construction of carriageways or footways with gutta percha, asphalte, asphalted felt, wood, or other suitable material or combination of such materials rendered impervious to water by a solution of caoutchouc or other solution suitable for that purpose. When such carriageways are intended for heavy traffic, he causes the same to be studded with metallic bolts, or with bars of iron, or rows of metallic bolts or studs; such rows to be placed transversely or at right angles to the line of traffic, at intervals of not less than three inches apart.

ONIONS' PORTABLE FORGE.

FIG. 1.

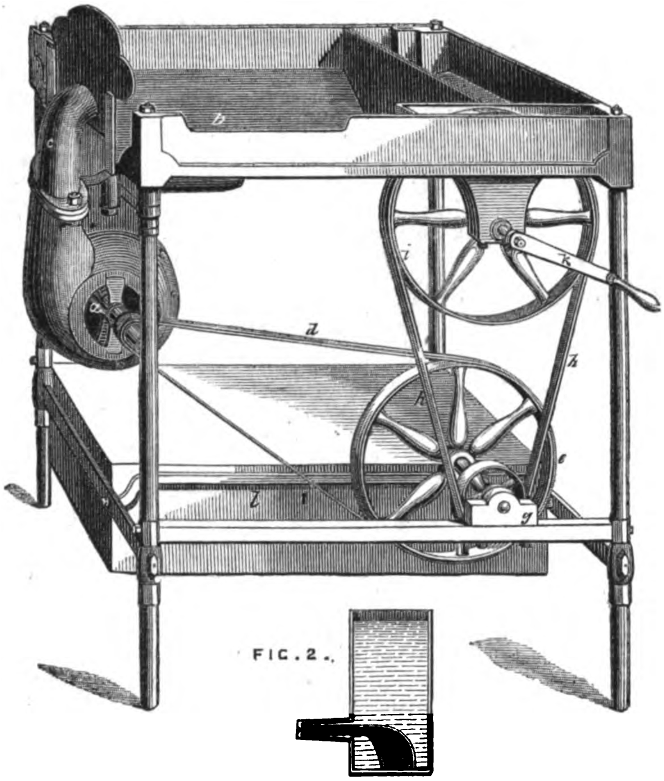

FIG. 2.

ONIONS' PORTABLE FORGE.

A **very** compact arrangement for a portable forge will be found described and illustrated as above. It is patented by Mr. J. Collingwood Onions, of Birmingham.

The invention consists in the employment of a fan for creating the blast, and in the arrangement of the parts hereafter described. The fan is placed under the hearth and at the back end of the forge, and the blast is led up into the fuel through a bent tuyere or pipe in which the upper part of the of the fan case is made to terminate; and the chest or box for holding tools is placed within the frame of the forge, and below the hearth. Motion is communicated to the fan by belts passed over pulleys driven by a crank handle or by toothed gear.

Fig. 1 of the accompanying drawings is an isometrical perspective view of a portable forge fitted according to this invention. *a* is the fan set beneath the hearth *b* of the forge; *c* is the bent pipe or tuyere, extending upwards as shown, for guiding the blast to the hearth. The tuyere is carried through a cistern containing water, whereby it is kept cool, as shown in the detached view below. Quick rotary motion is communicated to the fan *a*, through a strap *d*, passing round a wheel *e*, which is on a shaft carrying a pulley *f*, free to revolve in bearings in the frame *g* of the forge; *h* is another strap passing round the pulley *f* and a wheel *i* above, rotary motion being communicated to it through a handle *k*, or otherwise; *l* is a chest for holding tools placed and secured within the frame.

WALKER'S HARPOON SHIP-LOG AND SOUNDING-MACHINE.

Messrs. Walker of Oxford-street, Birmingham, have protected by letters patent two inventions—namely, a Harpoon Ship-log, and a Harpoon Sounding-machine.

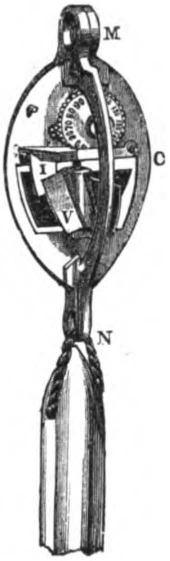
THE HARPOON LOG

Is an improvement on the older instrument, so well known as Massey's; for the rotator and the wheel-work registering the distance sailed are all in one instrument, instead of being distinct, as was formerly the case. By this arrangement the whole is rendered much more compact, and acts with greater accuracy at all speeds than when the two parts were distinct, and merely connected by an intevening cord. It is hardly necessary to state that, when in use, the log is attached to a line and thrown into the water, and is pulled onward by the advance of the vessel.

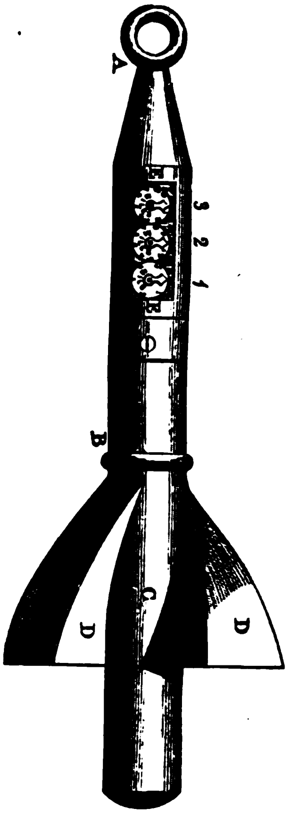
The part marked A and B in the accompanying figure does not revolve as it passes through the water, but contains the wheel-work for registering the number of revolutions of the rotator C, which is caused to revolve, as it passes through the water by the oblique position of the vanes D D. The angle of the vanes is so adjusted to the wheel-work of the register, that when the machine has passed through one mile, the finger of the first dial will have made one revolution; the finger of dial No. 2 will have made one-tenth of a revolution, and index No. 3 will have made one-hundredth of a revolution, or, in other words, the first index goes once round in one mile, the second index in ten miles, and the third in 100 miles. It will be seen that in this log the register and rotator are combined, the rotator being a continuation of the register or part that holds the wheel-work. By this arrangement, not only is the machine made more compact, but the end of the rotator is protected from all front-end pressure, thus considerably reducing the friction, and thereby enabling the log to register *with equal accuracy at all speeds*. Before throwing the log overboard, the finger or indexes, 1, 2, 3, should be placed at the beginning of their points of registry—namely, the first finger to 1, the second to 10, and the third to 100, then turn the outer loose tube E E round until the dials are covered. The rotators are in all cases made of solid seamless tube to ensure their being water-tight.

THE HARPOON SOUNDING-MACHINE

can be used with any common deep-sea lead. The rotator and wheel-work are completely protected from injury by the frame. When used, an ordinary deep-sea lead is attached to the lower end of the instrument by a rope N, the sounding line being fastened at the loop-hole M. The rotator in the centre of the machine it made to revolve, whilst descending, by the action of the water on its inclined vanes V; the locking piece I, being kept up out of the way by the resistance of the water. On reaching the bottom, the lock falls between the vanes of the rotator, and prevents it from registering while being drawn up. The first or small wheel which works in the worm makes one revolution in ten fathoms. The second or large wheel (shown in the engraving) goes once round in 150 fathoms. Before throwing out the machine, when using it, lift up the locking piece and turn the rotator until the small wheel stands at 10, and then, by means of the milled knob, turn the dial plate of the large wheel to 150, and the number of divisions the wheels will have moved when the machine is brought up again will show the depth. If required, these machines can be made to register any number of fathoms, or even miles, but for ordinary soundings 150 fathoms is considered sufficient.



Walker's Harpoon Sounding Machine.

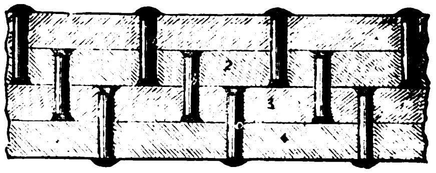


Walker's Harpoon Log.

CONSTRUCTIONS OF ARMOUR PLATING FOR VESSELS AND FORTS.

The annexed engraving shows a description of armour plating for vessels, and forts, &c., lately patented in this country by Mr. J. H. Johnson, being a communication from Filip Bergendal, of Sweden.

It consists in making armour plates of several



laminæ; but in lieu of connecting the whole of such plates together by bolts passing through the entire series, it is proposed to couple only the contiguous ones—thus, if four plates or laminæ be employed, No. 1 will be bolted, rivetted, or otherwise secured to No. 2, which in its turn is similarly secured to No. 3; this plate being secured to No. 4 plate, and so on throughout any desired number of plates. The accompanying drawing represents a section of an armour plate constructed in the manner above described.

1, 2, 3, 4 are the several component plates secured each to its adjoining plate by the three series of rivets *a*, *b*, and *c*. Any number of plates may be thus rivetted or bolted together to produce an armour plate of the strength desired.

ADMIRAL HALSTEAD ON MR. REED'S SHIPS.

Admiral Halstead has addressed an able letter to the *Daily News* on the "Enterprise" and other ships. He compares the "details of Capt. Coles's invention, and those of the plan derived from it," in the following language:—

Her cupola, instead of circular, is square; instead of revolving, it is fixed; instead of the form which gives greatest strength, it has that which gives least; instead of the form which requires least material in construction, it has that which requires most; instead of giving most protection with the lightest weight, it gives a less protection with a heavier; instead of doing most work with fewest guns, it demands twice as many guns to do no more than half the work; instead of carrying its own and its guns' weights centrally, so as to injure the ship's stability least, it carries them out to the extreme beam, where they will injure it most; instead of giving free intercourse from end to end of the working deck, it entirely obstructs intercourse by a barrier 30 feet wide and 7 feet high.

On the great question now so rapidly rising between central and broadside armament, the "Enterprise" mode of cupola-ship as jealously retains every disadvantage of the old system, as the true cupola gives free scope to every advantage of the new. For instance:—

Applying the proofs obtained from the trusty trials of Captain Coles's invention in September, 1861, when the gun from the cupola was found to fire with more certainty, and twice as rapidly, as the equal gun fired from a broadside port of the same ship, it follows, that either of the two pair of broadside guns of the "Enterprise" must be far from a match for the one pair of guns mounted in a true cupola. And even when fighting "both sides," since the true cupola, retaining its other advantages, can always revolve its fighting face from broadside to broadside within the time required for loading its guns, while the imitation can only fight its two pair of guns with half the rapidity of one pair, it follows again, that all the increased weight, labour, expense, complication, and liability to damage, in such ships as the "Enterprise," have to be incurred without a single concurrent advantage to compensate for what thus seems to be so ill-considered and retrograde a choice. On the contrary, while each of the two pair of guns in the imitation can command on each broadside a training arc of only 60 degs., it follows that the ship herself must be left without protection from broadside to broadside round by the bows, and the same again round by the stern, throughout two great arcs each of 120 degs., or nearly 11 points of the compass, within which points an enemy will find all but entire impunity. Let that enemy be a cupola-ship "Dexter," working her single pair of guns all round the compass, with all the advantages shown in the September trials, and it needs no prophet to foretell the early fate of her of the Bar Sinister. But, additionally, while the true cupola-ship can protect herself with all her guns all round the compass, without change of course or position, the "Enterprise," in order to protect herself throughout these 240 degs., or more than 21 out of the 32 points of the compass, can do so only by a change of course or position, which may not always be safe, and perhaps not even practicable.

I ought, however, to say, that, besides the four fixed broadside ports, there are narrow openings like ports—two looking forward and two looking aft—out of the very corners of the "Enterprise's" fighting-box, apparently to afford ingress and egress with the deck. A gun taken from the broadside might, on emergency, fire out of these openings at an angle of about 30 degs. from line of keel; but as no gun could be "fought" from them in any ordinary meaning of that word, their existence barely qualifies the entire impunity of the two great arcs described.

Proceeding to compare the respective features of the two modes of cupolas when actually under fire, we see as follows, viz.—the one presents a minimum surface to be aimed at, the other a maximum. The one deflects all ordinary shot from off a curvilinear surface, the other presents a rectangular face for receiving them in full force. The one opposes the penetration of any shot or shell with the increased thickness of wall due to its angle of obliquity; the other can oppose the full power of penetration by missiles fired direct, with the thickness of its wall only. Under a plunging fire, the one retains its advantages of impenetrability in size, deflection, and thickness, but exposes its top aperture; the other, with an equal aperture (for hoisting the guns in and out) exposes a penetrable flat roof, 36 ft. by 30, composed of 18-in. teak, covered with only half-inch iron.

Referring, in both cases, "strength of structure," irrespective of form, to the common standard of the "Warrior" target, we find as follows, viz.—the true cupolas of Captain Coles, now building, have one-inch thicker armour than the target, but the same backing and same inner skin. The "Enterprise" cupola has the same 4½-inch armour and the same 18-inch backing as the target, but no inner skin; so that the true cupola is stronger in structure as in form than either its imitation or the target; and the imitation is weaker in structure than both. Both in the target and true cupola the effect of the inner skin of iron is to prevent ignition of the wooden backing by shells, and intercept splinters; therefore the omission of this skin from the imitation renders it more fatal and combustible than either.

On the other great question now so rapidly rising—viz., the ability of ships to use guns far heavier than formerly, the "Enterprise" mode of cupola altogether ceases to be capable of comparison. If, indeed, the 95-cwt. solid shot 68-pounder be fit for fighting a sustained action at all, it certainly limits the weight of gun which is practicable upon the old broadside system of armament; whereas Captain Coles's cupola presents us, as regards both carrying and fighting, with the means of using at sea the heaviest reasonable gun yet projected, with a facility unknown throughout the broadside period. And on the all-important point of "training," whether it be for extent, ease, accuracy, or steady motion, it constitutes in effect the most perfect gun-carriage for heavy ordnance yet produced.

It will be noted that the professional judgment thus far offered has been strictly limited to the more direct mode and means provided in the "Enterprise" for fighting a successful action, and I resist as unnecessary all temptation to treat on those other less direct but important peculiarities she undoubtedly displays. For it will be granted that, whether large or small, armoured or bare, every war-ship, even if successfully designed for taking a special sphere of service, if she do not also take with her to that sphere the means of a successful fight against an equal foe, she may indeed be a bugbear to semi-savages, but for the strife of civilized warfare she becomes a great mistake.

I need, then, carry comparisons no further. I have, I think, adduced enough to prove that, under whatever motive or mere impulse the "Enterprise" was ordered, the study of her design could never have included any practical comprehension whatever of the special adaptations to modern progress which characterize that true invention she assumes to emulate, and doubtless was intended to surpass and supersede. But, I would ask, have I not also shown enough to prove further that sooner or later the day of trial must come when so many grave aberrations from sound practical judgment must inevitably present themselves for alteration and remedy; and that the larger the fleet of such ships to be sanctioned by the Estimates of this year, the larger the items for costly "conversion" stored up for those of the future? The "Enterprise" is now in that state when with least change of plan she may be made to cease exposing so many serious contrasts on so many fatal points, and when the wisdom of consulting for her immediate equipment with a true cupola mounting, say, a pair of the new Whitworth 150-pounders, will be attended with least loss of departmental—perhaps governmental—credit, as well as public money; while the country will the sooner possess an exemplar iron-clad small craft of true modern capabilities, instead of a vessel which on the very first comparative test to which she can be put is thus proved to be, however well intended, but a retrograde and inferior imitation.

Admiral Halstead then gives good reasons why experiments should precede shipbuilding on a novel plan:—Not a pound of powder has, he says, yet been burnt in proof of what protection could be given against modern missiles by that upper deck 14 in. of wood, and that main deck ⅝ in. of iron, which alone intervene between an enemy's shot, and no less than one-third of the guns and guns' crews of the "Black Prince," "Warrior," and sisterhood. But if the guidance of such powder-proof had been sought *before building* in 1859, when it must have shown the incongruity of such structures, we should not see the alterations now carrying out on the sister-ship "Achilles," at Chatham, as the sure guarantee and precursor of that same yet more costly operation to be performed in due time on the above two and the remaining four of the same incongruous family. An operation all the more sure, because so late as February, 1861, it was officially fixed that no alteration whatever should take place in the "Achilles," the actual drawings of the "Warrior" having been sent to Chatham for the express purpose of building her as "an exactly similar ship."

Again, even the armoured portion of the "Warrior" and her sisters was constructed on a mere guess. Not a pound of powder was burnt to prove beforehand if 4½-inch armour and 18 in. of teak, with an inner skin of ⅝ iron, would or would not be an equal substitute for the standard strength adopted from the "Trusty's" 4-inch armour and 25 in. of oak. And not till October 1861, when seven armour ships were thus built or building, did the trials of the "Warrior" target reveal to the guessers that their guess was a good one.

Again, not a pound of powder was burnt *before building*, to prove if the next guess of substituting 5½-inch armour with but 9-inch teak, would or would not give to the "Minotaur," "Agincourt," and "Northumberland," the same resistance as the "Warrior;" and this time the guess was a bad one. The late 12-ton 150-pounder Armstrong smooth-bore, which on the 8th of April and 20th of May last took so slight effect on the "Warrior" target, put its shot completely through the target of the "Monotaur" on the 7th of July following. But these three ships, representing when complete about £500,000 each, and they therefore remain as originally guessed at, to afford to those who fight them a less protection than their smaller and less expensive predecessors; as well as monuments to prove that mere guess-work may guide us to progress in the wrong direction.

Need I add that a few pounds, perhaps even cwts., of powder burnt *beforehand* to guide us to a safe choice of guns in 1858, must have saved the millions of money and loss of years which the Gun-proof Committee, so recently and tardily appointed, can never now redeem. For all the time and money so devotedly spent to uphold a choice, then so preferentially blind, finds our empire in 1863 with the great national land and sea services, so far as regards power of artillery against armour ships, and perhaps even in the field, practically gunless.—See Parliamentary Report on Ordnance, July, 1862, question 2,278; and compare with Shoeburyness trials of September the 16th and 25th, and November the 18th, 1862.

These, then are all grave warnings; all are of one nature; all point in one direction; all present to the country bills of cost equally as heavy as they ought to have been needless. Why so recklessly add to their number?

No less than four of this new species of cupola-ship, each of a different class, are already building. They vary from the 1000-ton "Enterprise," through the "Favourite" and "Research," up to the "Zealous" of 3,700 tons, with but four pair of guns upon each fighting face, and being quasi-armour-ships, £500,000 is a very low estimate for their cost; yet again, not one pound of powder has been burnt to prove *beforehand* the worth of one of them. Nor be it assumed that this new species can alone furnish us with small craft. There is now building in the Clyde a true cupola-ship for the Danes, armoured from end to end, instead of only very partially like the "Enterprise;" armed with two double-barrelled cupolas, and therefore of double her broadside force; with the same draft of water, and a burthen of 1,200 tons. If this vessel should realise all the cupola advantages of the September trials of 1861, then she must prove more than a match for the "Favourite" of 2,200 tons, also mounting but two pair of broadside guns on each fighting face of her fixed rectangular cupola, and roundly 1,000 tons larger than the Dane.

As before with comparisons, so now again with facts. I believe I have adduced enough to prove that guess-work and blind choice are bad and expensive means for solving those great physical problems which still surround us; and, instead of following such false guides any further, that it is far safer and more defensible to be led by the true light obtainable on our further progress from *proof as far as practicable*.

Deal, then, with this imitation in its present inchoate state, as the original was well and wisely dealt with before it was at all adopted. Utilise once more the "Trusty;" erect on her deck a *fac simile* of the "Enterprise" mode of rectangular cupola, and subject it to the same double proof of its offensive and defensive powers by as heavy and sustained a fire, from and against, as Captain Coles's invention underwent in September, 1861. If it come forth victorious, all unfavourable comparisons herein stated become mere words; but, if such practical proof be once more refused, then those comparisons must be held to be thereby substantiated, and known to be incapable of public or private refutation, except *by mere words*. In which case, those who rule highest in such matters will, it is to be trusted, see fit to direct, for the sake both of the country and its navy, that the further building of such ships should at once cease, as being incapable, in equal contest, of affording to those who must fight them any confidence of success.

SELLERS' PLANING MACHINES.

Mr. Sellers, of Philadelphia, the patentee this country of the well known screw-cutting machines, manufactured by Messrs. Sharpe, Stewart, and Co., of the Atlas Works, Manchester, has lately patented some important improvements in the construction of planing machines. We will more particularly describe his novel mode of working the rack on the planing machine table.

The nature of this invention consists in furnishing the table of the machine with a rack of the ordinary construction, and in operating this rack by screw gearing, which enables the driving shaft to cross the bed diagonally, passing out in a position near enough to the upright which carries the side rest and cutting tool to enable the driving belts to be within reach of the operator, and it also consists in transmitting and arresting motion by means of a ratchet, which must be the driver, and a double pawl attached to the object to be driven, so that while retained in gear with the ratchet, motion will be imparted to the object to be driven until by the interposition of a suitable stop the continuous motion of the ratchet will lift the pawl out of gear.

SELLERS' PLANING MACHINES.

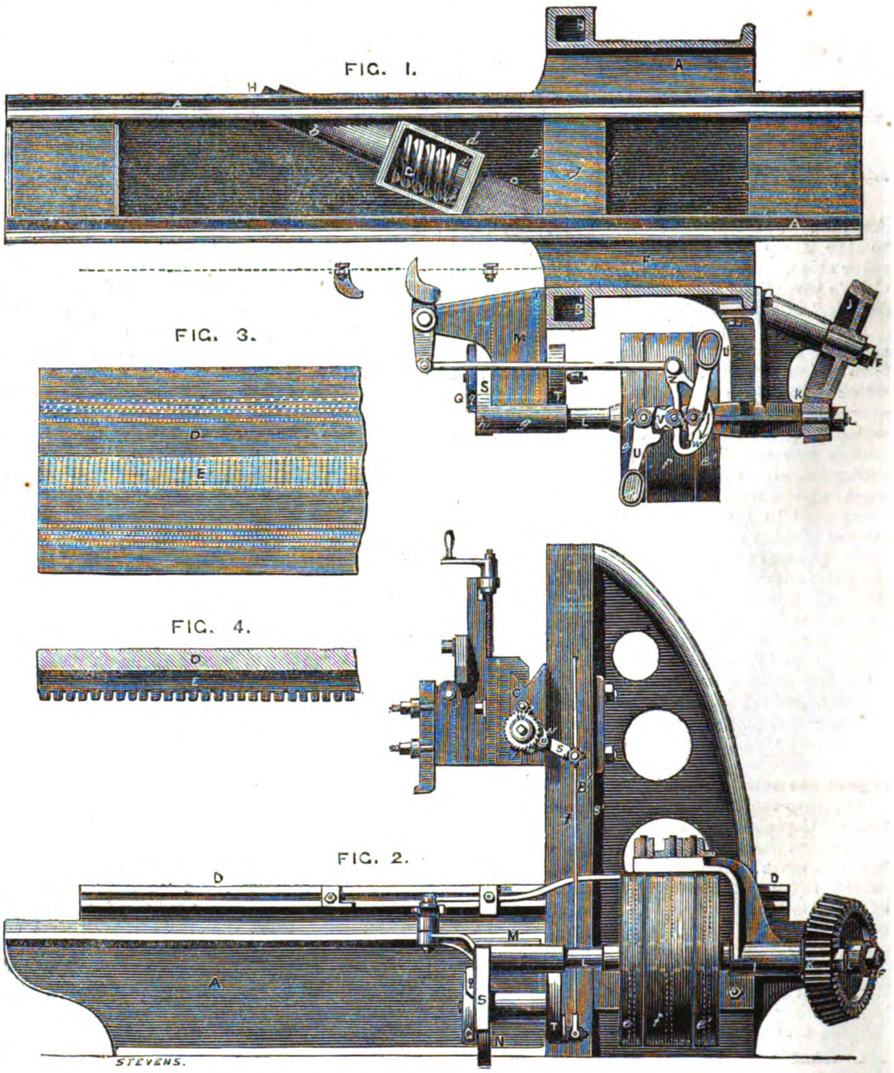


Fig. 1 represents a side elevation of a planing machine constructed according to this invention; fig. 2 is a plan of the machine with the table removed to show more clearly the parts below the same; fig 3 is a detached plan of a portion of the table; fig 4 is a section of the same.

A is the bed of the machine, to opposite projections of which are bolted the uprights B and B^1, carrying the slide C. The top of the bed A is provided with V-shaped grooves extending its entire length, in which slides the table D, it being provided with downward projecting ribs *a*, *a*, of corresponding bevel to the V-grooves. To the under side of the table and central between the slides *a*, *a*, and extending its entire length, is attached the rack E. Motion is communicated to the table by means of a worm upon a shaft F, crossing the bed diagonally (in the manner best seen at fig. 3), which worm G gears with the rack E. The driving shaft F revolves in bearings *b* and *c*, which are cast in the bed and connected by a trough *d*, serving as a receptacle for the lubricating material in which the worm G is kept constantly running. The end of shaft F in the bearing *b* receives a portion of the thrust from the motion of the table, under the cut against a step H, whilst a portion of the lesser thrust during the return motion of the table is received against the hardened collars d^1 and d^2, at the other end of G, d^1 being fastened against the end of bearing *c* and d_2, attached to the shaft F; the remainder and smaller portion of this thrust is received against the sides of the bearings *b* and *c*. The shaft F is at the end opposite to the step H, supported in a third bearing attached to a stand I, and outside of this bearing it is fitted with a bevel wheel J, which is driven from a pinion K on the pulley-shaft L, the latter having the usual fast pulley *f*, and loose pulleys *e* and e^1, transmitting alternately, by means of an open and crossed belt from the counter shaft above, the power for the reciprocating movement of the table. Upon reference to fig. 3, it will be seen that the position of the teeth in the rack of the table slightly varies from a right angle to the line of motion; this is done to counterbalance the side pressure which would otherwise be produced upon the table by the action of the screw under cut.

The advantages of the improvements, as regards facilities for bracing the bed in the parts under strain from the cut, will be obvious on reference to fig. 1. Here it will be seen that the sides of the bed directly between the posts and the uprights B and B are firmly braced by a box-shaped connection consisting of the vertical ribs *i*, *i*, and top and bottom plates *j* and *j*. To give the utmost capacity to the machine, it is very desirable to bring the driving belts clear of the uprights and within reach of the operator for convenience, and to accomplish this in the ordinary rack planer the space between the uprights is usually occupied by the gearing, and admits of a very narrow brace, and in the screw planer this brace must be much diminished in height to give room for the screw, so that the strengthening of the most vital part of the machine is rendered very difficult. In addition to the above braces, the bearings *b* and *c* of the shaft F, united by means of the trough *d*, connect the two sides of the bed in such a manner as effectually to strengthen it, and enable it to resist the end thrust of the shaft F.

HUMPHRYS'S MARINE ENGINES.

FIG. 1.

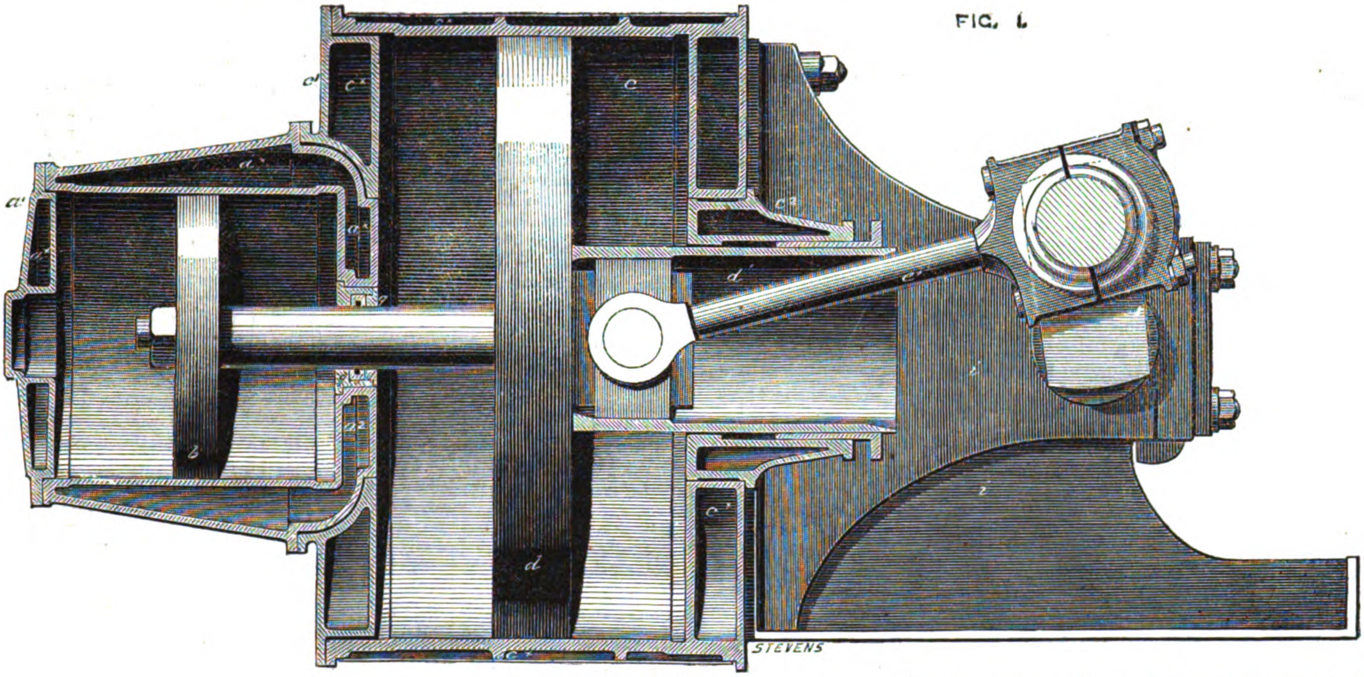

FIG. 2.

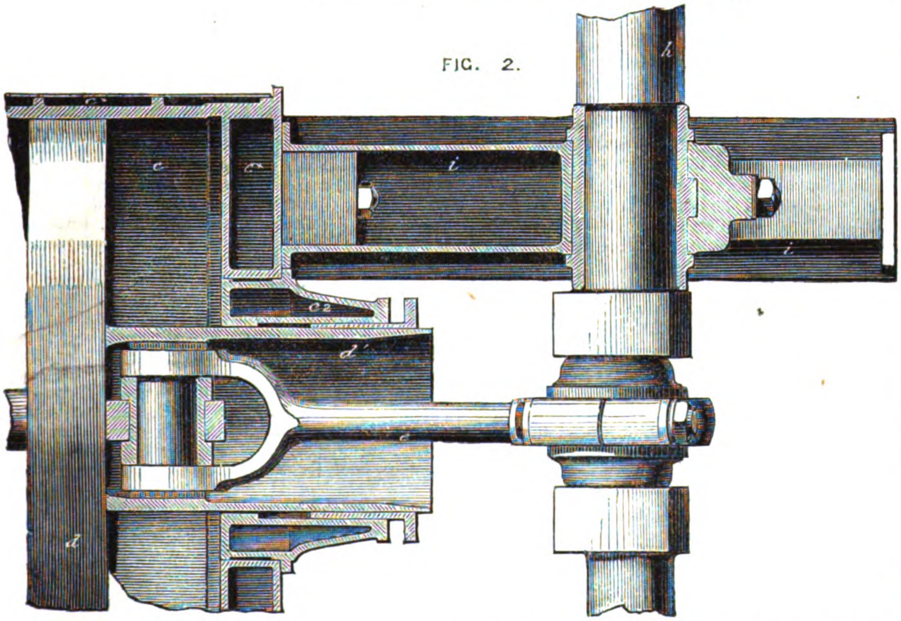

HUMPHRYS'S MARINE ENGINES.

THE following is a description of some improvements in marine engines, lately patented by Mr. Edward Humphrys, the well-known marine engineer, of Deptford, Kent. This invention has for its object improvements in steam engines, and relates to that description of steam engines in which two cylinders, a small one into which the steam first enters, and a larger one in which it is subsequently allowed to expand, are employed, and in which the pistons of the cylinders are connected together by a piston rod passing through the cover or partition which separates the small from the large cylinder. The improvements consist in applying a trunk to the large piston, and a suitable connecting rod, as in ordinary trunk engines, to transmit the power from the two pistons to a crank on a shaft or axis.

Fig. 1 is a side view, partly in section, and Fig. 2 is a plan, also partly in section, of a steam engine constructed according to this invention. *a* is the small cylinder to which the steam is first admitted, and *b* is its piston; *c* is the larger cylinder into which the steam is expanded after it has worked in the cylinder *a*, and *d* is the piston of the larger cylinder. Through the pistons *b* and *d* a piston rod passes, at one end of it the bearing is formed for the pin of the connecting rod *e*, and at the other is a nut to secure it on the further side of the smaller piston; *f* is a tube which surrounds the piston rod and keeps the two pistons at a proper distance apart; *g* is a stuffing box, by preference with metallic packing, it is formed between the two cylinders *a* and *c*, and the piston rod with the tube *f* work through it, the joint being steam-tight or nearly so. a^1 is the moveable end cover of the cylinder *a*, and c^1 and c^2 are the moveable covers of the cylinder *c*. a^x, a^x, and c^x, c^x, are steam spaces, with which it is preferred to surround the steam cylinders to prevent condensation. d^1 is a trunk formed on the piston *d*, it works steam-tight through a large stuffing box in the cover c^2, and the connecting rod *e* passes down within it. *h* is the cranked axle to which the connecting rod communicates the motion of the pistons, and *i* is a frame bolted to the end of the cylinder *c*, for supporting one of the bearings of the axle *h*, the other bearing or bearings may be carried in any convenient manner. The valves and other parts of the engine which are not shown in the drawings may be of ordinary construction.

THE ISTHMUS OF SUEZ.

FROM the latest reports, the great enterprise of cutting the Suez Canal is making satisfactory progress. This is altogether a French enterprize, and has therefore been "blown" upon by English writers, engineers, and politicians. According to some of those authorities, England is the only nation which has the right to undertake any great engineering work in any part of the world. If other nations attempt to imitate our example they are regarded as interlopers. Consequently, we are regarded by foreign countries as envious and selfish. All the hostile criticisms which have been offered in this country on the Suez Canal enterprize are supposed by foreigners to spring from poisonous motives. Had French authorities listened to our continual condemnations, they would have abandoned the enterprize long since. But they have throughout treated our opinions and judgments with something like indifference. It was optional, on our part, to have co-operated with them; but instead of doing so, we have, with Lord Palmerston at our head, adopted a scolding policy, with little effect, and with little credit to ourselves. If the latest account, as published in the *Times*, be correct, there are many predictions uttered in this country likely to prove false. Engineering science is too useful a thing in the world to be retarded or misdirected by political prejudices; and we earnestly hope that the great work which has been so persistently persevered in by the French Government will become an accomplished fact.

The correspondent of the *Times* says:—The works on the Suez Canal have undergone no interruption through the death of Said Pasha. About 20,000 men are at this moment either engaged upon the works or on their way to the isthmus, collected, as heretofore, from all parts of Egypt. To each party, as it arrives, a certain portion of the excavations is allotted, calculated upon an average of 40 cubic mètres for each man. The task is usually completed in about a month, when the men are allowed to return to their villages, generally carrying with them the trifling balance of their earnings that remains after paying the cost of the simple food upon which the Egyptian fellahs are content to live.

The efforts of the company are at present almost entirely directed to the completion of the canal, by which fresh water will be conveyed to Suez. It branches off, near Lake Timsah, from the small canal, previously dug by the company, and which, as your readers will remember, is a prolongation of the Wadi Toumilat Canal. The watercourse is about 25 ft. in width, with a depth of about 5 ft. It is already completed as far as the Bitter Lakes, and the engineers of the company expect to reach Suez before the middle of the coming summer. Their next task will be the construction of a feeding canal, starting from Cairo, and running along the edge of the desert, the execution of which, though lately abandoned, has been finally decided upon. Without it, indeed, it would be impossible to maintain a sufficient level in the new canals, even while draining their neighbours, to the grievous injury of the cultivators dependent upon the latter for the irrigation of their lands.

Having just returned from a visit to the Isthmus, I am able to speak of the impressions created by personal observation, and I confess that it is the inspection of the new fresh-water canals which seemed to me calculated to inspire the most lively interest. The sight of a stream of fresh water, flowing through the still and death-like solitude of the desert, of itself offers a most singular spectacle. A practical end can also more readily be assigned to this portion of the company's projects. To the inhabitants of Suez the acquisition of fresh water and of the attendant means of vegetation will be a boon of real value, and although new accessions of arable land are hardly yet an object of necessity to Egypt, yet the canals afford the prospect that many productive spots along their banks may yet be redeemed from the surrounding wilderness.

Between the fresh-water canal and the *rigole*, or preliminary trench of the maritime canal, runs a small channel, about 5 ft. wide and 5 ft. to 6 ft. in depth, which serves to supply the labourers with water, and which is lengthened as the work on either side progresses, being, however, always kept a short distance in advance. The cutting for the maritime *rigole*, through the ridge of the Serapeum, which, next to the Gisr, is the highest land on the course of the canal, I was informed, will for a short time remain in abeyance, while the fresh-water canal is pressed forward. The cutting of El Gisr has been dug to a depth, at its highest levels, of about 70 ft., and it forms a channel containing a width of about 25 ft., and a depth of 4 to 5 ft. The trench is cut, as elsewhere in the desert, with its sides at an inclination of 2 ft. for every 1 ft. in depth. The ridge terminates towards the north in a plain covered with hillocks of light sand, which, about four and a-half miles further on, sinks below the level of the sea, and is now covered with a shallow sheet of water, communicating with lake Menzaleh. It is along these four to five miles of the line that the canal appears to be exposed to the greatest danger from land-drifts. But it is maintained that the embankments which will be formed when the canal is excavated to its full width and depth will afford ample protection. As a further precaution, hedges of cane and brushwood are put up at various points across the plain. These, it is contended, will serve as barriers against the progress of the heavier particles of sand, which being raised by even the most violent storms at but a slight elevation, and moving at a low velocity, are brought to the ground on meeting with the least obstacle. The lighter particles, being lifted high into the air, are carried away over long distances, and on again falling to the ground are spread so lightly over the plain that it is contended they can be of little or no practical effect.

The track of the canal along the greater part of its course through Lake Menzaleh is clearly marked by the embankments, of which the bases have been raised on either side at a distance of 60 metres across. Two small channels have been formed, one on either side, with a depth of water just sufficient to give passage to a small boat. The central portion of the canal is still untouched, and the mud which forms the bed of the lake frequently shows itself above the surface of the water. The embankments are made of this same mud, which was lifted by hand labour from the bed of the lake. Near Port Said the traces of the embankment become very slight, and in some places our boat seemed to cross the open lake. The work is to be continued by means of dredging machines. The mud is raised in almost a liquid state, and is poured into a species of caisson formed of planks, supported by wooden piles driven into the bed of the lake. On rising above the level of the water, the mud hardens into a solid mass. This portion of the work, as will be readily believed, has been attended with great difficulties and trouble, but the worst is believed by the engineers to be past.

As the canal approaches Port Said it is to attain the width of 80 mètres, terminating in a basin or dock of 800 mètres square. This basin is likewise to be deepened by means of dredging machines. As yet only 16 machines have been put together at Port Said and along the canal, but I was informed that the number will shortly be raised to 50, and that each is expected to excavate an average of little, if at all less than, 1,000 cubic mètres a day.

The channel of communication with the sea will be 400 mètres wide, and its entrance is to be protected by a double jetty. The western mole is to be prolonged to a distance of 3,400 mètres, or somewhat more than two miles, where it will reach a depth of water of 10 mètres, or about 32 feet.

A small islet of stone has been formed at about half the distance as a nucleus to the future pier, and to serve for the discharge of the boats that come to Port Said with stone and other materials and stores. The temporary wooden jetty is about 200 yards in length, and is partially filled in with stone. The accumulation of sand that has been formed on the western side advances the beach to the extent of about 50 yards into the sea; but the engineers are disposed to attach but little importance to the matter. They argue that before the sand can reach the extremity of the mole, it must fill up an angle formed by a basis extending to an almost unlimited length along the coast to the westward, and of an elevation of upwards of two miles. The stone required for the works at Port Said has hitherto been brought at an exceedingly heavy cost from the quarry of El Meks, near Alexandria. Future supplies are to be drawn from the hills of Gennefieh, near the Bitter Lakes, and to be brought in flat-bottoned boats along the canal, at the estimated cost of 14f. the cubic mètre.

At Suez, it will be remembered, the intention of constructing jetties has been abandoned, and it is proposed simply to deepen the channel that leads from the anchorage to the town, a distance of about four and a half miles, and which is practicable for small boats alone. The channel is formed on its western side by a large sandbank, partially uncovered at low tide. At its further extremity the Messageries Imperiales have commenced the foundations of the dry dock, in accordance with their contract with the Egyptian Government. The dock will be connected with the shore by an embankment 2½ miles in length, already in course of construction, over the sandbank, and which will be surmounted by a railway. It strikes one as a singular thing, considering the implicit confidence with which the success of the Canal Company appears throughout to have been regarded by the French public of all classes, as well as by the late Viceroy, that it should not have been resolved to await the conclusion of the improved channel, when the dry dock might be constructed close in shore on a far more convenient spot, and, of course, at a very much lighter cost.

AXLE BEARINGS.

MR. N. J. AMIES, of Manchester, has lately patented a composition to be used for the bearings for carriage and other axles. It consists of animal fibre, plumbago, steatite, caoutchouc, or gutta percha, and any resinous gum or animal glue or size, the proportions being almost immaterial if the animal fibre be in sufficient excess; the composition being moulded or cut into the regular form.

Vegetable fibres have been similarly used before; but inasmuch as animal fibres, such as silk, wool, hair, or disintegrated skin or pelt are much more durable, and possess other superior qualities, the patentee employs it in combination with the aforesaid materials in contradistinction to vegetable fibres, as not having been hitherto so employed. In bearings, journals, or other frictional surfaces where water may be employed to assist in lubrication, he prefers to employ a resin or gum called "rhus copallinus" (gum copal), or a varnish made therefrom, as the medium to unite or bind together the other components, as such gum will best resist water in a heated state. The bearings, bushes, journals, steps, and other frictional surfaces are to be cast or otherwise produced with cavities, spaces, or excavations for the reception of the composition or filling, which is placed next to and in immediate contact with the shaft or wearing surface; or, if required, the composition may, in some instances, be used solid, without the support or combination of metal or wood. The composition will be found suitable for such purposes composed of silk, wool, hair, or other animal fibre (either in a fibrous state or reduced to a pulp), two parts; plumbago, steatite, or similar lubricating or antifrictional material, half a part; and resinous substance, gum, or varnish, half a part; or in such other proportions as circumstances may require.

ARTILLERY EXPERIMENTS AT SHOEBURYNESS.

A SERIES of interesting experiments with Whitworth, Armstrong, and Lynall Thomas guns against various thicknesses of armour plates, were tried on Tuesday at Shoeburyness. The experiments were conducted by Capitain Alderson, R.A., under the command of Colonel Taylor, R.A., and the guns were aimed by Lieutenant Reeves, R.A.

The target was altogether stronger and made of finer iron than any yet experimented upon. The plates were of the best rolled iron which could be made by a manufacturer of such eminence as Mr. Brown, and it was universally admitted that in the quality of the iron and method of working they could not be surpassed. They were of three different thicknesses upon the target, the upper plate being 5½ inches thick, the middle one 7½, and the lowest 6½ inches. The target was about 12 feet square, and for about half of its breadth the plates were backed with teak planking, varying in thickness slightly from 9 to 6½ inches behind the thickest plate, so as to allow the face of the target to be plane. The other half of the target was left entirely without backing, in order to test the value of this timber support, which it will be remembered is in the "Warrior" and "Achilles" 18 in. thick, and in the "Minotaur" only nine. The plates were bolted on to the skin by 2-inch bolts, fastened with screw-nuts, the large heads of which were in this instance protected from the great concussion by three washers of gutta percha and one of lead. The skin was of the usual thickness, ½-inch, behind the thinner plates, but it was made 2 in. thick to support the heavy 7½-inch armour plate. Besides all this came very strong ribs and transverse bracings of wrought iron, with an immense crosspiece running the whole breadth of the target, which we could not describe better than by the name of the manger, which it got before the day was out. There was no chamber behind this target, as in that which the Whitworth shell penetrated, but it was merely shored up by enormous balks of timber, to which it was braced, and which transferred their burden to the bank of earth behind. It will be seen, then, that this target was altogether as strong as iron could make it in anything like a ship's side; but as to the wood backing, it was weaker by half than the other targets experimented upon, and than the "Warrior."

The range at which all the guns were fired was 200 yards. The practice commenced with shots fired to try the plates, and ascertain the comparative effect of 68-pound shot and the same weight of shot sent from a rifled gun. In this way three shots from the 68-pounder service gun with 16 lb. of powder were fired, producing the usual dents in the plates. The three shots which followed, and produced precisely the same effect, were fired from Sir W. Armstrong's 110-pounder service gun with oblong steel shot, as proposed by Ordnance Select Committee, the charge being 16 lb. of powder. The next shot was from the Armstrong 300-pounder muzzle-loader rifled gun, weighing 12 tons, with a solid steel shot of 300 lb. and a charge 45 lb. of powder. This struck the middle and thickest plate right in the centre, and almost in the bull's-eye, producing a large dent of three inches in depth, and slightly cracking a rib behind. The velocity, as given by Navez's ballistic apparatus, was 1,290 ft. per second. The same gun was next fired with a 300lb. steel shell, containing a bursting charge of 11lb. It struck the 5½-inch plate at the left-hand corner, pierced it, and burst in the wood backing, cracking the skin, and breaking three or four strong ribs, besides knocking the heads off some rivets and breaking off one bolt. The wood was set on fire also. No part of the shell, however, had come through into the ship, so to speak, neither were there many pieces of the skin scattered about; the general shaking of the whole mass, however, was evidently considerable, and quite enough to settle the fate of the "Minotaur" in the face of such a weapon. The velocity of this shot was given as 1,310 ft. per second. The Whitworth gun was now tried with a 148 lb. shell of the description used in former experiments in November last, with a charge of 25 lb.; it penetrated the 5½-inch plate about 4 in. to the right of the hole made by the Armstrong shell, and burst in the wood, but without getting through the skin. The noticeable point in this experiment was that the smaller and lighter gun, with half the weight of shot and powder, did almost an equal amount of mischief. The bursting charge of this shell was 5¼ lb. It was this gun which sent its shell through the 5-inch plate and timber backing at 600 yards' range.

Mr. Lynall Thomas's monster gun was now to be tried. On the whole its accuracy was very good, and we heard no reason given for the one shot which missed the target. This gun weighs 17 tons, and is a muzzle loader rifled, and of nine-inch bore. After two scaling charges of 50 lb. of powder, a 320 lb. shot was fired; it struck the ground at the left-hand corner of the target, carried away part of the bank behind, and, amid a storm of earth, flew with a loud roar away to seaward. The gun was loaded again with a solid projectile, 18 in. long, having three spiral grooves on it to fit corresponding fillets in the bore, and weighing 370 lb., with a charge of 50 lb. of powder. This time the target was hit at the junction of the 7½ and 6½ in. plates, a large dent of 3½ in. deep was made, and the plates were considerably cracked, but nothing went through. The shot rebounded about 25 yards, and when fished out of the ditch was found to be "set-up" several inches, so that it looked like a huge cauliflower, the stalk being the end which did not strike the target. The velocity of this shot was given as 1,300 feet per second.

A solid tempered steel shot of 328 lb. was then fired from this gun with a 50 lb. charge; it penetrated the 7½-in. plate to the wood, just at its lower border, and grazed the 6½-in. plate; the plate was cracked, as well as the skin, a bolt was broken, and the manger was knocked completely off on to the ground. The velocity of this shot was given as 1,250 feet per second.

The last shot was from Sir William Armstrong's rifled shot gun, with a 150 lb. spherical smooth shot, with a 45 lb. charge. This struck the 7½-in. plate where there was no backing, cracking it widely, starting the bolts, and penetrating to 3½ in. It shook the whole structure severely, and bulged the plate extensively, but did not get through the plate. The general opinion seemed to be that the target had been subjected to so much pounding that the later experiments were not worth much, and that it would have been much more satisfactory if Sir William Armstrong's heavy shell had been fired at the thickest, instead of the thinnest plate. Another point appeared to be that no thickness of armour a ship could carry would be proof against these heavy steel shot. The experiments excited the greatest interest, and the day being beautifully fine there was a large gathering of scientific artillerists.

TO CORRESPONDENTS.

Received.—C. C.—Capt. N.—G. C.—G. B.—D. H.—C. B. A.—N. B.—Mac. A.—Bross and Co.—D. and S.—G. N. D.—W. P.—W. R. T.—T. R.—S. S.—W. and Co.

T. G.—The letter is much too personal, verbose, and insulting for our pages. The first letter has not been received.

L. M.—Thanks.

Tyro (Huddersfield).—The total steam power in England was estimated by Dr. Fairbairn as equal to that of 8,000,000 horses, besides 3,000,000 horse power afloat.

F. S.—"Truran on the Iron Manufactures of Great Britain" is the best work on the subject.

D. H.—You will find that a number of patents have been taken out for hydraulic cranes, &c., both before and after 1846, the date of (Sir) W. G. Armstrong's patent (No. 11,319). T. Crowther, in 1852 (No. 14,340), took out a patent for a self-acting crane. See No. 1888, year 1855; No. 812, year 1856; also No. 967, year 1856 (taken out by Sir W. G. Armstrong). See also No. 1768, and No. 2,356, year 1858; also No. 644, year 1859. A more prolonged search would probably reveal to you several more patents of this description.

F. P.—By applying personally and carrying good testimonials with you, you may succeed; good interest, however, is better than the highest merit in this case.

T. S. (Ipswich).—The angle formed by the sides of Mr. Whitworth's standard V threaded screws is 55 deg.

MR. REED AND CIVILIAN.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

Sir,—Having for many years taken great interest in all matters relating to the British Navy, and having attentively read the able articles and letters which have from time to time appeared in your valuable paper having reference thereto, I shall be glad if you will give insertion to a few words from me on Mr. Reed's ships, and your correspondent "Civilian's" remarks thereon. It appears to me, as of course it must to every one of your numerous and intelligent readers, that the only object we have in view is to arrive at the truth in this all-important question of iron-plated ships. Now, from the general tone of "Civilian's" letters, I gather that he is, from some cause or other, of which, of course, I am ignorant, rather opposed personally to Mr. Reed than to the principle upon which that gentleman's ships are being constructed. It is, I think, impossible for any impartial person to read "Civilian's" letter on the new Chief Constructor of the Navy, in your impression of the 27th ult., without coming to this conclusion. He there endeavours to show how probable it is that Mr. Reed knows next to nothing of the theory and practice of shipbuilding, and speaks of "a Watt, a Lang, a Turner," and "a Moody," as though they were the Cæsars or Alexanders of the profession. I would also remark that such phrases as the "Reed scheme," "the fighting box," and the "new born chief," when used in the manner in which "Civilian" uses them, appear to me to show the animus of the writer, and, to say the least, are not indicative of impartial controversy. When "Civilian" does touch upon the *demerits* of Mr. Reed's ships (of course they have no merits), he seems to think he has proved an important point when he has shown that the "Enterprise," a ship of about 900 tons burthen, is not so strong inch for inch, and does not carry in proportion so great a weight of armour as the "Warrior;" but surely everybody knew this before; and the suggestion of "Civilian" to submit the "Enterprise" to a target trial is simply absurd. We all know pretty nearly what amount of battering her sides will stand, and we know also that the simple production of a target to keep out shot and shell is not the only desideratum in a sea-going ship of war. If Mr. Reed has given us a ship of less than 1,000 tons burthen, plated from stem to stern in the region of the water line with 4½-inch armour plating, and capable of carrying amidships four 110-pounder armour-protected rifled guns having a nearly fore and aft range of fire, rigged as an ordinary ship of war, and capable of bearing the flag of Old England to the antipodes; I say, if Mr. Reed has given us this ship—and of this there appears to be little, if any doubt—he has given us what we had not got before, but what we certainly wanted. I was glad to find your able and impartial correspondent, Mr. Cheverton, dealt with this subject in your number of the 6th inst.; he undoubtedly discusses the matter fairly, honestly bringing forward both sides of the case, and he has done much to develop the truth.

I do not believe in any conspiracy on the part of the Admiralty to waste the public money by building wooden ships. They are feeling their way cautiously and prudently; and I have no doubt that, if it be finally demonstrated that wood is in every way inferior to iron for the construction of ships of war, they will discontinue building ships of wood, and resort entirely to iron. One thing, however, is certain, viz., that scientific problems cannot be solved by fierce partisanship and one-sided reasoning.

I am, &c.,
Observer.

PATENT LAW REFORM.

Sir,—I beg leave, before I lay my scheme of *Patent Law Reform* before your readers, to make some additional remarks. There is, as I believe, every prospect of this subject being substantially investigated by the Commission, and considerable alterations in the Patent Laws are anticipated. How far Parliament may be disposed to adopt the Commissioners' Report is, at least, questionable, and I allude to this as a check to sanguine expectations on the part of inventors. The subject is, as I have before observed, a difficult one, involving cross interests—those of the public on the one hand, and those of inventors on the other hand.

It is my intention to devote this letter to one point. The point I refer to is this—*i. e., the questionable validity of a patent.* All patents are questionable on the two following grounds, viz.:—

1. The *novelty* of the invention.
2. The *validity* of the patent itself.

1. *The novelty of the invention.*—By the present law this is left an open question. A patentee, or his assignee, may manufacture for several years without opposition, and presently may be surprised with an "infringement." In other cases, a patentee, or his assignee, manufactures under the supposed validity of his patent amidst a constant "storm of opposition." What is to be done to remedy this state of things? The best suggestion I can make is to exercise greater caution before making application for a patent. The remedy for this mischief is, to a great extent, at least, in the hands of the applicant, and this cannot, as I think, be too well understood by patentees.

2. *The validity of the patent itself.*—This branch of the subject will, I trust, receive careful and thoughtful consideration by the Commissioners. It is a hard case to have a patent upset on the ground of validity—that is, the invention being one for which a patent will not lie. The subtleties of the celebrated "Statute of Monopolies" still pervade our system of patent law—this Act being, in fact, the basis of such system. A case illustrative of this "hardship," for such it really is, is now pending in the Court of Chancery, being an injunction suit. It is surely contrary to *moral principle* that the fees should be taken upon an instrument which may turn out, when "put in suit," to be valueless. This is a branch of the subject to which I beg leave to call attention, and which it is desirable to devise a remedy.

In conclusion, sir, let me mention that the sense of my last letter is much embarrassed by some verbal inaccuracies. The blame, to some extent, is, I must acknowledge, with myself for indistinctness in penmanship. With your permission I will lay my scheme before your readers in my next letter, and I propose to do so with as much simplicity as practicable.

I am, &c.,
T. Culverhouse.

3, Compton-street, Ball's-pond,
March 10, 1863.

STEAM PLOUGHING.

Sir,—In your article on the "Great Steam Plough Trial," Mr. Bovill, the leading counsel on the plaintiffs' side, is reported to have said, "When the patent of Messrs. Fiskin was taken out, the problem of ploughing by steam was solved, and the first approach was made to the construction of a really useful and serviceable steam-plough." You add these words—"To this we fully agree." Then let me call your attention to the 19th March, 1855, the date of my steam-plough patent. Hundreds of these ploughs are now in useful and serviceable operation, and my own farm has been regularly worked by it ever since December, 1855. The Messrs, Fisken's patent is dated July 19, 1855, just four months behind mine. Now I shall not go into the question as to whether my plough that turns at the land's end is to die out to make room for the double action one of the Messrs. Fiskin; but I shall and do claim the honour of having been the first to solve the problem, and stand here before you as king upon the question of steam-ploughing. Yes, and if I may be permitted to live a few years longer, I shall see the double action thing a dead letter, for a thing that can live only by working its engine at double its nominal power must die. England stands first and claims the honours.

I am, &c.,
William Smith.

Woolston, Bletchley Station, Bucks,
March 16, 1863.

P.S.—The balance principle depends more upon the clip drum than it does upon itself, for all other modes of application have already failed.

Meetings for the Week.

Mon.—*British Architects*, at 8 p.m.
Medical, at 8.30 p.m.
Royal Geographical Soc.—I. "Kurrachee to Gwadur, on the Mekram Coast, in the Cold Season of 1861-62," by Major F. J. Goldsmid, F.R.G.S. II. "On the Harbour of Ledashagur, by Dr. D. Macpherson, at 8.30 p.m.
London Inst.—"On Music," by Josiah Pittman, Esq., at 7 p.m.

Tues.—*Inst. Civil Engineers.*—I. "Description of the Lydgate and of the Buckhorn Weston Railway Tunnels," by J. G. Fraser, Esq. II. "The Public Works in the Province of Pernambuco, Brazil," by W. M. Peniston, Esq., at 8 p.m.
Royal Inst.—"On Animal Mechanics," by Prof. Marshall, at 3 p.m.

Wed.—*Soc. of Arts.*—"On the Present Sources of Supply of Quinine, with Special Reference to the Introduction of the Chinchona Plant into India and other Countries," by C. R. Markham, Esq., at 8 p.m.
London Inst.—"On the Zoology of the Warm-blooded Vertebrata," by C. C. Blake, Esq., at 7 p.m.

Thur.—*Royal Inst.*—"On Chemical Affinity," by Dr. E. Frankland, at 3 p.m.
Inst. of Naval Architects.—"On the Naval Architecture of the Exhibition of 1862," by Vice-Admiral Paris, C.B. "On the Construction of Iron-plated Ships," by W. Fairhairn, Esq. "On Iron-plated Ships," by J. D'A. Samuda, Esq. "On Modern Guns and Iron-coated Ships," by J. Scott Russell, Esq., at 12 a.m.—Evening Meeting: "On the Steering of Ships," by N. Barnaby, Esq. "On Copper and other Sheathing for the Navy," by W. J. Hay, Esq., at 7 p.m.
Numismatic, at 7 p.m.
Antiquaries, at 8.30 p.m.
Royal Soc., at 8.30 p.m.

Fri. — *London Inst.*—"On Economic Botany," by R. Bentley, Esq., at 7 p.m.
Inst. of Naval Architects.—"Experiments with a Rotating Ship Clinometer," by Prof. C. P. Smyth, F.R.S. "On the Rolling of Ships," by J. Scott Russell, Esq. "On the Resistance of the Medium as Limiting the Angles of Rolling," by W. Froude, Esq. "On Isochronism of Oscillation in Floating Bodies," by W. Froude, Esq. "On Iron-clad Sea-going Shield Ships," by Capt. Cowper P. Coles, R.N., at 12 a.m.—Evening Meeting: "On Iron and other Masts and Spars," by C. Lamport, Esq. "On Framing Iron Bulkheads," by G. C. Mackrow, Esq. "On the Protection of Iron from Oxidation and Fouling," by W. J. Hay, Esq., at 7 p.m.
Royal Inst.—"On Phallium," by W. Crookes, Esq., at 8 p.m.
Architectural Association.—Class of Design. Chalice, Flagons, and Paten.
Philological, at 8 p.m.

Sat. —*Inst. of Naval Architects.*—"On the Education of Naval Architects in England and France," by J. Scott Russell, Esq. "On H.M. Yacht 'Fairy,'" by T. J. Ditchburn, Esq. "On Measuring the Strain on Ship's Cables," by T. M. Gladstone, Esq. "Differential Wave in a Stratified Fluid, with an Experimental Illustration," by W. Froude, Esq., at 12 a.m.
Royal Inst.—"The Science of Language," by Prof. Max Müller, at 3 p.m.

Gossip.

On Saturday, the 14th inst., the London Association of Foremen Engineers celebrated their tenth anniversary by a dinner at the Bay Tree Tavern, City. Mr. W. H. Keyte presided. The dinner was as usual—excellent. The loyal toasts were given, and able speeches were delivered. The principal event of the evening, however, was the presentation of a testimonial to Mr. Joseph Newton, of the Mint, in recognition of his services to the Institution during the four years he has been President. The testimonial consisted of several articles of plate, including a salver, an inkstand, and a card tray. They bore the motto, "Reap as you merit." The inscription engraved on the salver was: "To Joseph Newton, President of the London Association of Foremen Engineers. This testimonial is presented as a token of esteem, 14th March, 1863." Mr. Newton expressed his thanks in a suitable speech. We are glad to learn that the Association is in a most flourishing condition.

Her Majesty's steam sloop "Spiteful," Commander Wilson, from the West Indies, was paid off at Woolwich on Saturday. When at Havannah her crew were attacked by yellow fever, of which no less than fifty men, including six officers, died. On the voyage home; a man who fell overboard was saved by Clifford's lowering gear. The poor fellow was unable to swim, and had already disappeared, when the boat was manned and lowered, and in three minutes the drowning man was in the boat, safe. This is another instance of the rapidity by which a boat may be lowered by this invention, and is due to the fact of the entire control of everything resting with one man, and not being the result of the divided duty of several, as in lowering by the falls.

The ordinary meetings of the Institution of Naval Architects for 1863 will be held at the Society of Arts on Thursday, Friday, and Saturday next. Sir John Pakington will take the chair. Papers of considerable interest will be read by Vice-Admiral Paris, of the French Navy; Dr. Fairbairn, Mr. Scott Russell, Captain Cowper Coles, Mr. W. Froude, Professor C. P. Smith, Mr. N. Barnaby, Mr. J. W. Hay, Mr. G. C. Mackrow, Mr. T. M. Gladstone, and others.

Mr. Alderman Waterlow has commenced a work worth imitating in Finsbury. He has just finished a block of improved buildings for the working classes. These buildings are substantial; and each family compartment contains the conveniences requisite for a working man's home. The great want of London and other cities is better house accommodation for the mass of the people. Model lodging-house schemes have not been attended with success—partly, we believe, because they have carried with them too much of the philanthropic element, and too little of the economical element. There is no reason why good, substantial, well-ventilated dwellings may not be provided at a cheap rate; and great credit is due to Mr. Waterlow for the useful enterprise he has commenced.

At the Mersey Dock Board on Thursday, on a question of substituting "cradles" for "blocks" in repairing ships, it was said that the very act of repairing them by the latter method was the means of putting them out of repair. Blocks force the ships' caulking so much that they are frequently found to be leaky after undergoing a thorough repair.

The Scotsman says that at Limekilns, Fifeshire. on the 10th inst., some persons were desirous of showing their loyalty by firing a salute, but a serious obstacle presented itself, in the fact that no such thing as a piece of artillery existed in the place. A local genius set to work, however, and in a short time had fabricated a cannon out of ropes which he coiled tightly in the shape of a tube. The experiment was highly saccessful, the salute being fired without accident.

The lighthouse recently erected at Allepey, in Travancore, India, on the coast of Malabar, is distinctly visible from the Ghaut mountains at the great distance of 54 statue miles. It is a holophatal revolving white light. The lenticular portion of the apparatus was made by Messrs. Chance, of Birmingham, and the lantern and machinery were made by Messrs. Milne, of Edinburgh, all from designs by Messrs. Stevenson, civil engineers.

Application has been made to Parliament for power to construct a footway bridge over the river near the Tower. We understand that, in consequence of the opposition of the wharf owners to the bridge, from its interference with the navigation, the engineer, Mr. Barlow, has proposed for the same estimate to construct an iron subway or tunnel under the bed of the river at the same spot.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

The Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

Steam Engines, &c., 2324, 2337, 2338, 2343, 2353, 2358.
Boilers and Furnaces, 2317, 2321.
Roads and Vehicles, including railway plant and carriages, saddlery and harness, &c., 2325, 2344, 2354.
Ships and Boats, including their fittings, 2316, 2345, 2352,
Cultivation of the Soil, including agricultural implements and machines, 2312, 2364.
Food and Beverages, including apparatus for preparing food for men and animals, 2320, 2360.
Fibrous Fabrics, including machinery for treating fibres, pulp, paper, &c., 2308, 2314, 2318, 2323, 2331, 2335, 2350, 2355, 2365.
Buildings and Building Materials, 2362.
Lighting, Heating, and Ventilating, 2311, 2313, 2315, 2341.
Furniture and Apparel, including household utensils, time-keepers, jewellery, musical instruments, &c., 2309, 2319, 2328, 2332, 2340, 2342, 2347, 2363.
Metals, including apparatus for their manufacture, 2336.
Chemistry and Photography, 2330.
Electrical Apparatus, 2334.
Warfare, 2310, 2349, 2351.
Letter-Press Printing—*none*.

2307. H. Garside. *Improvements in machinery or apparatus for marking, etching, or engraving on cylindrical and other surfaces.* Dated August 16, 1862.

This invention consists—1, In the employment for marking, etching, or engraving upon cylindrical surfaces of two frames used in connection with a pentographic arrangement, from which pentographic arrangement motion is imparted to the said frames by means of two slots, bars, grooves, or slides, one of which is attached to each frame, and which said slots, bars, grooves, or slides cross each other at right angles, and receive motion from the pentographic arrangement at their point of crossing over or intersection with each other. One of these frames carries or communicates motion to the marking, etching, or engraving points or tools, in a direction parallel with the axis of the cylinder operated upon, and the other frame moving at right angles to the foregoing, imparts all of such rotary movements to the cylinder as may be necessary in combination with the straight line movement of the marking, etching, or engraving points or tools to produce upon the cylinder the figures desired. 2, In the employment for marking, etching, or engraving upon cylindrical or other surfaces of two frames or tables, carried by or moving upon wheels or rollers, and actuated by a pentographic arrangement. The lower of the two frames or tables is constructed to move in a direction at right angles to the axis of the cylinder operated upon; and the second table which rests upon, and is carried by the first, and partakes of its movement, is capable of being moved thereon in directions parallel with the axis of the cylinder. 3, In the employment for engraving machines for cylinders of a castor for supporting the arm of the pentographic instrument which carries the traction point, in lieu of the suspension cord, over head pulley, and balance weight hitherto used. 4, In the employment for engraving on flat or irregularly formed surfaces of a system of tools, actuated by means of voltaic electricity in combination with electric magnets attached to, or connected with, such tools. 5, In the employment of magneto-electricity for the generation of force to be used in actuating or withdrawing the tools or instruments employed for marking, etching, or engraving on cylindrical or any other-formed surfaces, such force having been hitherto generated by means of voltaic electricity. *Patent completed.*

2308. C. H. J. W. M. Liebmann. *Improvements in machinery for finishing textile fabrics.* Dated August 16, 1862.

This invention relates, chiefly, to machinery employed in producing what is technically known as the whirlpool finish upon textile fabrics, and for which letters patent were obtained by Isaac Beardsall, dated Dec. 12, 1855 (No. 2807); also for similar machinery by Charles Weiss and Henry Lister, dated March 20, 1857 (No. 781). The action or operation of this machinery upon the fabrics is intermittent, or by intervals of time for action and for moving the fabric forward in the machine, and these changes have to be effected by hand. Now these improvements consist in combining, arranging, and applying apparatus or parts to effect these changes by mechanical means at suitable intervals. For these purposes worm are fixed in the upright shafts which operate the tables gearing with wheels in which are stud pins, to which are attached rods connecting to the table, so that at each revolution of the wheels the table will be lifted and lowered. Another stud in one of the worm wheels operates a lever to put in or out of motion the rollers which carry the fabric through the machine, so that when the table is raised motion will be given to the fabric, but when the table is lowered the fabric will be at rest. Also a catch and notch plate are applied and geared in such a manner that one revolution thereof will cause the fabric to move forwards the width of the table at the proper distance required. These improvements are also applicable to machinery employed in the finishing of Witney cloth, and in machinery for napping and frizzing textile fabrics. *Patent abandoned.*

2309. T. Knowles and W. Robinson. *Improvements in racks for window blinds.* Dated August 16, 1862.

In order to adjust the cord of the window blind to the requisite place and tightness, the inventors introduce an endless elastic band, made of vulcanized india-rubber, or other suitable material, the said elastic band passing over the ordinary roller knob and a stud sliding in the groove of the rack in the usual manner, so that, when the knob and stud are adjusted to the proper place or position, according to the length of the cord, the said elastic medium connecting the knob and stud gives an additional spring or elasticity to allow of knots, snarls, or other irregularities that may occur in the cords. They use the said elastic endless band either inside or outside the rack, as may be found most desirable. *Patent abandoned.*

2310. M. Iturriaga. *Improvements in fire-arms.* Dated August 16, 1862.

This invention consists of certain improvements in connection with fire-arms, whereby a great number of shots may be simultaneously and consecutively discharged from one arm, the arm itself being fastened around the body of the soldier, and concealed, if desired, by a coat or cloak. The arm is constructed as follows:—A segmental or semicircular bar of iron or steel of a square section is pierced or bored at its periphery in four or other number of rows, so as to form a number of barrels, on the same principle as the revolving chamber of a repeating pistol, the breeches of all the barrels in each separate longitudinal row communicating with each other by the medium of a channel or groove. The interior periphery of the segmental series of barrels is provided at or about the centre thereof with four or other number of nipples, according to the number of rows of barrels, set obliquely under each other, one nipple serving for the discharge of one entire segmental row of barrels. This segmental or simicircular series of chambers is then to be fixed in a metalic belt by means of slots or grooves cut obliquely vertical therein, and into which corresponding projections on the segment slide, so as to hold the series of barrels firmly thereto. Either the right or left side of the belt is provided with a lock, and a handle or trigger, which actuates the main spring, and raises the hammer simultaneously, and discharges the same upon the uppermost nipple of the series; after renewing the motion of the handle a lever acts upon projecting studs behind the segment, and slightly raises the same obliquely upwards in the belt bringing the next nipple underneath the hammer, which is, consequently, discharged, exploding the second series or row of chambers in like manner to the first; so also the third and fourth or other number of rows may be discharged. The arm may be made in two semicircular divisions, so as to form a ring completely encircling the body of the soldier, and enabling him to discharge projectiles in every direction around him. *Patent abandoned.*

2311. S. A. Bell and T. Higgins. *Improved apparatus for dipping lucifer matches.* Dated August 16, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2312. G. Chapman. *Improvements in reaping machines.* Dated August 18, 1862,

This invention relates to the arrangement and construction of a mechanical movement for effecting the removal of the cut crop from the platform of the reaping machine, and depositing it at the side of the machine. Under one modification, or system of arrangement, a square pillar, or standard, is fitted to a convenient part of the reaping machine, and in the rear of the cutter. This pillar is fitted with a slide, which traverses freely up and down it. This slide is fitted with a laterally-projecting stud, on which is carried the lower end of the lever that extends upwards above the main pillar, and is then bent at right angles, so as to extend over the platform. To the free extremity of the overhanging lever is attached a pendent rod, carrying at its lower end a rake, or flat blade. Motion is communicated to the overhanging lever from any convenient moving part of the machine which is suitable for driving a crank, or other equivalent therefor. On the stud, or axle, carrying the crank is a pendent lever, which has a bend formed in it at about one-third of its length from the stud, or axle, on which it is centred. At this part an eye is formed in the overhanging lever, and through this eye the bent part of the lever passes, which serves as the connection of the two parts. To the lower end of the pendent lever is fixed a laterally-projecting rod, which has a link at its outer extremity that encircles the rod carrying the rake. With this arrangement, when the crank is put in motion, the pendent lever moves the rake laterally in a horizontal direction to a certain extent, which is limited by the position of the bend. After reaching the extent of its traverse in a lateral direction, the bent part of the lever acts as a fulcrum by which the overhanging lever is raised, carrying with it the rake which moves in a curved direction across the platform, and descends on the other side to the point from whence it started. Thus the motion of the crank and the pendent lever causes the main overhanging lever to rise and fall, and at the same time traverses in a lateral direction, the slide on the pillar admitting of the vertical motion, and the pendent lever regulating the lateral movement. These eccentric or compound movements cause the rake to traverse in an elliptical path, so as to sweep off the grain from the platform. The rake then rises out of the way as another portion of the crop is being cut, descends on the other side, and again clears the platform, and so on continuously. *Patent abandoned.*

2313. T. Barnett. *An improved lamp or lantern for street lighting and other purposes.* Dated August 18, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2314. J. Cimeg. *Improvements in depositing silver and other metals on fabrics and other materials.* Dated August 18, 1862.

The patentee states that he has discovered it is possible to mordant fabrics, and similar soft fibrous materials—as, for example, silk, leather, and paper—in such a manner as to cause the silver, gold, or platinum, to adhere firmly to their fibres, so that it will not rub or wash off. He can also, by mordanting portions of a fabric, and afterwards bringing it in contact with a suitable solution, cause the silver, or other metal, to adhere only to the mordanted portions of the fabric, and thus he can imprint on a fabric any form of pattern in firmly adherent metallic silver or metal. Many vegetable juices (more especially those which are acid to the taste, and contain simultaneously a small amount of tannin, or a matter acting like tannin upon chemical reagents, such as currants, sorbs, and other berries, apples, pears, &c.) have, more or less, the property required. For the sake of brevity and clearness, he explains the proceeding by means of a particular example. Supposing there were ten grammes of loose silk to be silvered, the first thing to be done is a complete cleaning of the matter from all foreign substances, like grease, gum, colouring matter, &c.; now the matter is to be macerated in from 50 to 60 grammes of juice of the above-mentioned fruits, which may be stewed for winter use. The required reaction takes place immediately after the immersion: it is, therefore, only necessary to see that, all parts being thoroughly wet, the washing of the matter in distilled water be perfectly done; the said reaction cannot be destroyed any more by washing. All solutions of whatever metals proper to the metallization of glass may be applied in this case, but the solution which he prefers for depositing silver is a mixture of ammonia, nitrate of silver, and Rochelle salt. *Patent completed.*

2315. J. T. Oakley. *Improvements in heating stoves employed for drying and other purposes.* Dated August 18, 1862.

In carrying out this invention it is proposed to employ the steam from any common steam boiler or steam generator, or to use the steam from the exhaust pipe of a steam engine, and by a suitable pipe or pipes to conduct it to a superheater, which it is proposed to build either within the boiler furnace, or within some portion of the boiler brickwork, with a separate furnace, or to erect the superheater and furnace separately, and by the application of fire in the furnace, or of gas suitably applied, to produce heated vapour of the temperature required, and to convey such heated vapour through suitable pipes or flues of iron, firebrick, or earthenware to the stove or stoves to be heated. *Patent completed.*

2316. W. E. Newton. *Improvements in connecting plates, sheets, or slabs of metal, or other materials, and fastening the same on to framing applicable to armour-plating for ships, vessels, or batteries, and to roofing, and other similar purposes.* (A communication.) Dated August 18, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2317. J. Briere. *A continuous, self-acting condenser, being a new system of boiler-feeding apparatus.* Dated August 18, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2318. H. Boetius. *Improvements in fire-proof materials.* Dated August 18, 1862.

This invention consists in the application of a fibrous material, known as asbestos, in combination with fire-clay or plumbago, or both, for the manufacture of fire-proof ware—such as crucibles for melting ore, steel, brass, or other homogenous metals, pots for melting glass or other fire-proof ware. *Patent abandoned.*

2319. H. Melton. *Improvements in the manufacture of hats and caps.* Dated August 18, 1862.

This invention consists in certain improvements in hats and caps, the object of which is to enable them to present two different surfaces to the weather, or in other words, to make their surfaces reversible, in order that in fine weather a cloth or woven surface may be exposed, and a water-proof material or enamelled leather surface in wet weather. The inventor proposes to form the hat or cap with a double crown and rims, one of which is to be of cloth or other woven fabric, the other to be of a water-proof material or of enamelled leather. Each of these crowns and rims are to be sewn at opposite ends of the body of the hat or cap to the extent of half the circumference, and then the two remaining halves of the crowns are to be sewn together so as to form one piece, presenting a cloth surface on one side, and a water-proof surface on the other side, which may be drawn over either of the halves of the crown and rim, which are sewn so as to expose an entire cloth surface, or an entire water-proof surface as desired. To facilitate the movement of the reversible portion of the cap, a gusset is made on each side thereof, and an elastic cord keeps the gusset closed. Through the fixed cloth surface of the crown, two or more holes may be cut for the purpose of ventilation. *Patent abandoned.*

2320. T. Wilkinson. *Improvements in machinery or apparatus for singeing pigs.* Dated August 19, 1862.

This invention consists of an iron chamber open at both ends, and having its interior longitudinally furnished on opposite sides with tubes perforated so as to emit jets of gas. Sufficient room is left in the centre of this chamber for the carcases to pass through between the gas jets on either side. Running longitudinally through the chamber, and near the top which has an arched roof, is a trap supported on uprights at either end, upon which is placed a small truck, and this is set in motion by an endless chain passing through the chamber. This chain runs through wheels at both ends. The pigs are run from the truck, and the motion which the wheels of this truck acquire in passing along the track communicate to the carcases hanging from the truck a rotary motion while passing through the chamber between the ignited gas jets, so that on issuing forth at the opposite end they are perfectly singed. The whole machinery is put in motion by a windlass which is in immediate connection with the endless chain above referred to. The gas is supplied to the jets by a single large tube on either side. *Patent abandoned.*

2321. V. F. Cleuet. *An impoved self-acting apparatus for supplying boilers with water, applicable also to the raising and to the measuring of liquids.* Dated August 19, 1862.

This apparatus consists of a hollow vessel or float immersed in liquid contained in another vessel or case, which float in alternately filling and emptying becomes in turn heavier or lighter than the liquid which surrounds it, and partakes of itself of alternative vertical motion, whereby it is placed in successive communication with the boiler and the feed supply, to transfer from one to the other the water necessary for the generation of steam. *Patent completed.*

2322. G. H. Dembinski. *A motive apparatus, and processes proper for giving to it a continuous motion and unlimited strength.* Dated August 19, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2323. S. Bouctier. *Improvements in flax spinning, which improvements are also applicable to spinning of tow and hemp.* Dated August 19, 1862.

This invention consists in adapting to ordinary machinery employed for spinning flax, tow, and hemp, a reservoir to contain water of any desired temperature, and in immersing and leaving therein during the spinning operation the bobbins containing the flax or other material to be spun The aforesaid reservoir is placed at the upper part of the spinning machine, and the material is drawn from the bobbins immersed therein by the spinning machinery. By these means the process is rendered considerably more healthy for the workmen, and less costly than the modes heretofore practised of treating flax, tow, and hemp during the spinning thereof. *Patent completed.*

2324. W. J. Hoyle and J. Proven. *Improvements in mechanism and arrangements for supplying lubricating matter to the cylinders of steam engines, and to the bearings and other surfaces of mechanism.* Dated August 19, 1862.

This invention consists—1, in mechanism by which lubricating matter can be supplied to cylinders of steam engines at regular intervals, by self-acting means, during the time that the steam is entering the cylinder, at one or both sides of the piston; such mechanism consisting of a pump, which draws lubricating matter from a cistern and forces it through a valve into the cylinder, or into passages leading to it. The valve is arranged so as to be acted upon by a weight or spring of sufficient force to prevent it from being opened by the suction of the exhaust in condensing steam engines. The pump is actuated by weights or springs—that is, a small weight is employed to lift the piston or plunger of the pump to draw in the oil or lubricating matter, and a large weight is employed to force the oil or lubricating matter into the cylinder, the large weight being sufficient to overcome both the small weight, friction, pressure of spring acting upon the valve, and the pressure of the steam in the cylinder or passages leading to it. The large weight is lifted by mechanism acted upon by some oscillating or reciprocating part of the engine; but when the pump is not required to act, the small weight is prevented from descending, and when the pump is in action, the duration of its action for each stroke of the piston is determined (if required) by a stop which prevents the descent of the large weight below a fixed point; or an adjustible amount of play is allowed between the pump ram and the small weighted lever which lifts it so that the length of its stroke can be varied, and thus the quantity of lubricating matter injected may be regulated. *Patent completed.*

2325. T. H. Falkiner. *Improvements in the permanent way of railways.* Dated August 19, 1862.

This invention relates to an improved mode of securing the fish-plates or other contrivances for connecting the rail ends of permanent way together, and consists in forming upon the ends of the bolts employed two screwed portions or lengths, the one being of larger diameter than the other, and the threads on each portion being in reverse directions, the one portion being a right and the other a left-hand thread. On each of these portions a nut corresponding to it is screwed—that on the inner screwed portion serving as the ordinary or tightening nut, whilst that on the outer portion, which is of less diameter, being screwed in the reverse direction, serves the combined purposes of jamming the inner nut and also of counteracting the tendency of the bolts to turn loose. *Patent completed.*

2326. J. G. Tongue. *Improvements in processes and apparatus for extracting the natural wax or fatty matters from wool, hair, or other animal or vegetable substances, containing the same, and in the application thereof to various useful purposes.* (A communication.) Dated August 20, 1862.

The wool, fats, or grease known in commerce, contain, besides the "suint," a certain quantity of fatty acids which result from the decomposition of soap used in certain manufactures, together with the small quantity of oil or grease, which is added to wool, in order the better to work it, and may be separated according to this invention, so as to obtain products of considerable value. This is accomplished by means of spirits of wine or alcohol, of a high degree of strength, or pyro-ligneous spirit, and the application of heat. The fatty matters to be treated are dissolved in either of these spirits, and a fatty or waxy substance termed "suint" is precipitated. The alcohol employed may be easily removed and restored by distillation (as described), together with the alcohol which holds the fatty acids in solution. The fatty acids may be employed alone or in combination with other fatty substances in the manufacture of soap. *Patent completed.*

2327. W. Whittle. *The manufacture of nails and spikes by improved machinery.* Dated August 20, 1862.

For the purposes of this invention, to form blanks, the rods are passed into a machine in a cold state, and a portion of the said rod of a sufficient length to form a nail or spike is cut off. It is then held firmly between a pair of dies, one of which is stationary and the other moveable, whilst the heading tool advances and forms the head. The moveable die then recedes, and allows the nail or spike blank to fall from the machine. The blanks thus formed have no points—that is to say, they are of the same size, excepting the heads, as the rods from which they are cut. The same process may be performed while the rod is in a heated state, but the patentee prefers using the rods in a cold state. The blanks thus formed are then inserted at the ends intended to be pointed into a suitably arranged furnace containing fuel in an ignited state, and urged to a white heat either by mechanical means or by the draught produced by a chimney stack. The blanks are then withdrawn by the workman, and while in a highly heated state are inserted between the dies of a forging or pointing machine, the said dies being formed to suit the taper of the points to be given to the nails or spikes. There are four dies or tools in this machine, which may be arranged to work in pairs in planes at right angles to each other—that is to say, two of them may be made to advance in opposite directions in a vertical plane, while the other two are receding in a horizontal plane, thus alternately beating or compressing the nail or spike on the two opposite sides; or there may be two moveable and two stationary dies used for the same purpose. *Patent completed.*

2328. C. Callebaut. *Improvements in sewing machines.* Dated August 20, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2329. H. Whittaker. *Improvement in healds or heddles, and in the manufacture of the same.* Dated August 20, 1862.

This invention relates to that description of heald in which are used short wires containing the eyes instead of cords or bands. The improvements consist in attaching to each of the ordinary shafts a shaft or rod which carries the short wires containing the eyes by means of a split ring passing through a hole at each end of each wire, by which arrangement the wires will yield to the action of the yarn; any of the wires can be replaced, and the wires can be separated from each other, for allowing the hand to be passed between when required. *Patent abandoned.*

2330. W. Hutchinson. *Improvements in the manufacture of ammonia and the prussiate of potash or soda, and in apparatus employed in such manufactures.* Dated August 20, 1862.

This invention consists, first, in the manufacture of ammonia and the prussiates of potash or soda from the refuse gluten and nitrogenous matters of starch and other manufactories. To obtain the ammonia the gluten or other matters are subjected to destructive distillation, in retorts made of suitable materials, with lime or soda and lime, from which the gaseous products are conducted to suitable condensers. The crude liquor thus obtained may then be purified by adding an acid, and crystallizing by filtering or re-distilling. The prussiates of potash or soda are obtained by fusing the gluten or other matters in an iron pot or retort with potash or soda. The fused mass is then lixiviated with water, filtered or decanted, and the prussiates of potash or soda are crystallized from the solution. The prussiates of soda or potash are also obtained by passing the gaseous products evolved from the gluten or other matters when subjected to destructive distillation over a mixture of charcoal and potash or soda and iron heated to redness. The charcoal is then lixiviated with water and treated as before. Secondly, the invention consists in certain improvements in the apparatus for the manufacture of ammonia and the prussiates of potash or soda from any suitable nitrogenous substances. *Patent abandoned.*

2331. J. Standish and T. Gooden. *Improvements in machinery or apparatus used in the preparation of cotton, wool, flax, or other fibrous materials to be spun.* Dated August 20, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2332. S. Wilkes. *An improved attachment for door knobs.* Dated August 20, 1862.

In carrying out this invention, the angles of the square spindle, to which the fixed knob is secured in any well-known and approved manner, are tapped so as to form a male screw. The removeable knob is also tapped so as to form a female screw to receive the tapped square spindle in the way commonly practised. The removeable knob having been screwed on to the spindle and brought up to its required position thereon, the knob and the spindle are locked or secured together in the following manner:—On the neck of the knob two projections of the width of the spindle are formed, and when these projections are brought into line with two sides of the square spindle, a solid plate or clamp having a slot cut therein is dropped and embraces both of the projections on the knob, and the square spindle thereby securely attaches the knob to the spindle and locks the two parts together. The slotted plate may, if desired, be retained in position, and also hidden from view by the rose or washer which is usually introduced between the door and the knob. *Patent completed.*

2333. C. Chinnock. *An improved construction of cork-screw.* Dated August 20, 1862.

This invention relates to a novel construction of cork screw, which combines the simplicity of action of the common cork screw with the advantage of lever power of the more costly double action cork screw. It consists simply of the common cork screw (formed, by preference, with a broad knife-edged thread) fitted loosely in a frame, which is intended to rest on the neck of the bottle from which a cork is to be withdrawn. The screw being pointed, and of suitable length, will, on the fixed handle of the screw being turned, first pass down into the cork until its descent is arrested by the frame. The turning being still continued, the frame will then act as a purchase, and the cork will be caused to rise up the screw into the frame. *Patent abandoned.*

2334. S. J. Paris and W. Bate. *Improvements in alphabetical electric telegraphs.* Dated August 21, 1862.

The documents relating to this invention are with the law officers under objection, and cannot at present be seen.

2335. J. C. Schemmann. *Improvements in the manufacture of steel.* Dated August 21, 1862.

This invention consists—first, in manufacturing steel in a granular and spongy state, by withdrawing it from the puddling furnace at particular stages in the process of puddling, and plunging it in cold water. Second, in manufacturing refined steel by enclosing the granular steel (obtained as described) in iron or steel cases, submitting the same to welding heat, and subjecting the cases and their contents to hammering, as described. *Patent completed.*

2336. M. Wilkinson. *Improvements in carding engines, parts of which improvements are applicable to drawing and such like frames.* Dated August 21, 1862.

In carrying out this invention, the inventor firstly applies to the carding engine a cage-like apparatus of peculiar construction a convenient distance below the lower part of the main cylinder, and a somewhat similar apparatus in the same way below the lower part of the licker-in, for the purpose of preventing the greater part of the loose or short fibres of the cotton or other fibrous substances from falling amongst the dirt or other refuse of such fibrous substances, which would have otherwise been the case, and thereby causing the greater part of the said loose and short fibres of the cotton or other fibrous substances to be preserved and more advantageously used than otherwise would have been, thereby causing a great saving in such fibrous substances. Secondly, he applies an improved apparatus for stopping the motion of the carding engines, or of only stopping the motion of the feeding apparatus of such carding engines when the carding ceases to be regularly supplied, or when a larger quantity or lump is attempted to be delivered to the delivery rollers than is required. Thirdly, he applies the last-named apparatus to drawing frames, for the purpose of stopping the said machines, when the quantity delivered from the front drawing roller is defective, or the sliver breaks between the drawing rollers and the delivery rollers. *Patent abandoned.*

2337. G. Davies. *Improvements in governors for steam engines.* (A communication.) Dated August 21, 1862.

This invention consists in combining a spring with a governor spindle, and rods are arranged so as to form a knee-joint, so that the force applied to overcome the rigidity of the spring may be transmitted through a leverage constantly increasing as the resistance of the spring increases, thereby equalizing the action of the said spring—a desirable object to be attained under certain circumstances. The weighted arms of the governor are hung to the top of the spindle in the usual manner. To the weights of the arms are jointed the upper ends of rods, the lower ends of the latter being connected to a sleeve which is fitted snugly to, but arranged to slide freely on, the spindle. A spring is connected at a point midway between its opposite ends to the spindle by means of nuts, which are adapted to the screwed portion of the said spindle. To one end of the spindle is jointed a rod, and to the opposite end a similar rod, each rod being connected to a coupling by means of a nut, one of these couplings being connected to a lug on one side, and the other to a lug on the opposite side of the upper end of the sleeve. The lower end of the latter has a recess for receiving the end of the usual governor lever, through which the movement of the sleeve is communicated to the throttle valve of the steam engine. This recess being formed by two collars, one of which is fast to the sleeve, the other being screwed on to the same, as is also a nut, the striking of which against a nut screwed on the spindle limits the downward movement of the sleeve, and consequently the inward movement of the weights. *Patent completed.*

2338. T. Clements, P. Llewellin, J. Llewellin, and J. Wanklyn. *Improvements in the construction of a self-acting lubricator for lubricating various parts of steam engines.* Dated August 21, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2339. A. Boubee. *Apparatus for casting or moulding glass, and for imitating precious stones or marbles.* Dated August 21, 1862.

This invention consists of apparatus for the purpose of casting glass and mingling the same with enamel, in order to form objects in glass, coloured or not; and also objects presenting the appearance of polished ornamental stone. The inventor proposes to use a mould formed in two halves, which are connected together by a hinge or a spring joint, in order that the molten glass from a furnace may be poured or placed therein, and compressed by a screw or clamp so as to receive the shape of the mould. *Patent abandoned.*

2340. A. Boubee. *An improved veil proctector.* Dated August 21, 1862.

This invention consists of a small elastic cord or band, the two extremities of which are passed through an ornamental metallic tube or tag, furnished with a hook; the ends of the cord being then knotted are retained by the tube. When the veil is adjusted on the bonnet, the elastic cord is stretched thereon and drawn down on each side by the tags, and the hooks are then brought to bear upon the cheeks of the bonnet, whereby the elastic cord is secured, and the veil prevented from being blown back beyond the line of the cord. *Patent abandoned.*

2341. S. F. Griffin. *Improvements in apparatus to be used in the distillation of petroleum, or any oleaginous, resinous, or alcoholic bodies.* Dated August 22, 1862.

This invention is not described without reference to the drawings. *Patent completed.*

2342. A. Whytock. *Improvements in making boxes and preparing sheets for the same.* Dated August 22, 1862.

Provisional protection has not been granted for this invention.

2343. C. Monson. *A new and useful repeating rotary engine.* Dated August 22, 1862.

This invention is based upon the principle that the same current which, when confined under pressure, will revolve one wheel or instrument, may be caused to so operate a larger number successfully, that the aggregate power of the whole, or the useful effect thereof, shall be increased, such current being either of a liquid, aeriform, or a gaseous character. *Patent completed.*

2344. W. Barrett. *Improvements in casting railway sleepers and chairs where tie-bars are used.* Dated August 22, 1862.

These improvements are applicable when casting chairs which have hollow inverted sleepers, similar to those known as Greaves', through which when in use tie-bars are passed and secured by keys. When making a mould for the casting of a chair and sleeper of this description, cores are used to produce the requisite holes in the castings for the passage of the tie-bars; this is usually done by forming prints on the pattern, which produce depressions in the sand into which the core separately moulded is afterwards fitted. Now, in place of making the core for the purpose of producing the hole as heretofore, it is, according to the present invention, made in two parts—one part is of iron, and the other of sand. The portion which is of iron is (when covered with loam) moulded in the upper box on the convex surface, which is produced in the lower box in the same manner as the other parts of the mould. Thus it will be seen that the core is formed complete in the upper and lower boxes, and has not, as heretofore, to be laid in as a separate piece between the two after the pattern has been drawn and the mould is otherwise complete. By this method the holes are cast perfectly clean and true, and require no fitting, as the tie-bar will pass through the holes readily, and the ends where the gibs and cutters come are also as true as possible. Time and labour also is saved in the moulding. *Patent completed.*

2345. E. S. Ritchie. *Improvements in the mariners' compass.* Dated August 22, 1862.

This consisrs in the arrangement and combination of an air vessel with the magnet, or with the same and its card, in manner so as not only to encompass the magnet or magnets, and completely insulate the same from the surrounding liquid, but also to buoy up the card and magnet, or the magnet or magnets, or remove more or less of the weight thereof from the pivot. *Patent completed.*

2346. J. Mackay. *Improvements in the manufacture of soap powder.* Dated August 22, 1862.

This invention consists, according to one modification, in combining together the following, or proportional quantities of the following ingredients—viz., 20 cwt. of soda crystals, 1 cwt. of best yellow or pale soap, 1 cwt. of pearl ashes, 1 cwt. of black or pot ashes, 10 to 20 gallons of water, 1 cwt. of soda ash, 7 lb. of palm oil, 7 lb. of sulphuric acid, 7 lb. of sulphate of soda, and 7 lb. of chloride of lime. The ingredients are all mixed together in a boiler, and boiled by means of a direct fire, or by means of steam, for about five hours, after which the compound is spread out in shallow troughs to cool, being continually stirred until cooled. The resulting product is a granular or or more or less crystallized powder, in which state it is packed for sale. *Patent completed.*

2347. R. Harrington. *Improvements in umbrellas and parasols, and in the manufacture of parts thereof.* Dated August 22, 1862.

We cannot here give space to the details of this invention. *Patent completed.*

2348. H. Twelvetrees. *Improvements in the preparation of washing powders, soap powders, and cleansing crystals.* Dated August 22, 1862.

This invention consists in combining glycerine, or extract thereof, or other oleaginous and fatty matters, such as are used in or suitable for the manufacture of soap, with other ingredients or materials in the manufacture of soap powders, washing powders, and cleansing crystals. *Patent completed.*

2349. D. Moore. *Improvements in breech-loading fire-arms.* Dated August 22, 1862.

The nature of this invention consists in double breech-blocks, one sliding on the line of the barrel, and the other at right-angles thereto, in such a manner that the transverse moving block draws away from behind the longitudinally moving block, and that draws away from the barrel for introducing the cartridge, and is forced up again to the rear end of the barrel, and the laterally moving block comes up behind it to sustain the explosion. To effect this operation the patentee makes use of a peculiar lever, acting upon these blocks in such a manner that, by a simple movement forward or back, the two blocks are slidden, and the breech opened or closed by the one motion of the lever; the said lever is not connected to either block, hence one can stand still while the other block is moved, and *vice versa.* The invention cannot be fully described without reference to the drawings. *Patent completed.*

2350. G. Bottomley. *Improved apparatus for expressing moisture from pulpy or solid substances.* Dated August 22, 1862.

This invention consists in the employment of perforated and grooved plates of metal, or other suitable material, between which suitable quantities of the substance to be operated upon are placed, and then submitted to pressure. *Patent abandoned.*

2351. D. Moore. *Improvements in revolving fire-arms.* Dated August 22, 1862.

This invention relates—1, to a means for attaching the stock, barrel, and cylinder, so that the said cylinder can be swung aside from the stock for the purpose of loading or removing the charge from the piece, but when in position for firing the said parts are held firmly together. In all the arms of this character, in which a rifled barrel is employed, the ball has been slugged or forced into the rifle grooves in the barrel. The ball as it is discharged from the chamber in line with the barrel meets with the obstruction and comparative detention caused by the said rifling, and the recoil of the powder acts to produce an opening between the front end of the chamber and the rear of the barrel, causing escape of gases or "windage." This invention obviates this difficulty, and relates, 2, to forming the forward end of each chamber with a rifled surface, corresponding to the grooves in the barrel, so that the ball entered with the cartridge is slugged previous to entering the barrel, and the explosion and the detention of the balls in being forced into the rifling cause the chambers to press firmly against the rear end of the barrel, thereby cutting off and preventing as much escape of gas as possible. This revolving breech fire-arm is formed with chambers open at the rear end to receive cartridges, with a metallic capsule containing the powder and receiving the ball, a hollow flanged ring being provided for the fulminating material around the base of the cartridge. *Patent completed.*

2352. W. Carwood, W. Boaz, and C. Colwell. *Improvements in apparatus for propelling ships and other vessels.* Dated August 22, 1862.

In carrying out this invention, the patentees construct propelling apparatus in such manner that they produce centripetal action, by which the water is, so to speak, gathered inward, and then expelled in the direction of or in a line with or parallel to the propeller shaft. For this purpose, they set on a propeller-shaft blades or vanes shaped like sections or portions of a hollow sphere, and presenting their concavities in the opposite direction to that in which the vessel is to be propelled; they are so set that, if the full spherical figure of which they are sections were completed, those spheres or full figures would intersect their outermost edges, which are of increasing pitch. They thus exert a confluent action on the water, and produce centripetal force, which gathers the water towards the axis, the water being expelled, as described, contrary to what has hitherto been done by screw propellers, which have exerted a centrifugal action. The blades may be adjustable on a boss, so as to be set at the desired angle in respect on the shaft, and so that they, and hence the vessel's direction, may be reversed. In this case, the boss is not a fixture or the shaft, but is loose thereon, being connected with it by a clutch. The blades most frequently lie transversely to and obliquely on the shaft. *Patent completed.*

2353. T. WOOD. *Improvements in slide valves of steam engines.* Dated August 22, 1862.

The object of this invention is to reduce the friction, and, consequently, the power required to work the slide valves of steam engines. The invention consists in forming an elastic diaphragm in the upper slide and over the exhaust cavity of the valve, which elastic diaphragm is intended so that of itself it would not support the pressure of the steam acting upon it, but it is supported or sustained by a plate placed under the diaphragm, connected with or resting upon anti-friction wheels, pulleys, or rollers which work upon prepared surfaces; or the plate under the diaphragm is connected with one end of a rod, the other end being jointed with a fixed centre. The elastic diaphragm may be formed of metal, india rubber (suitably prepared and protected), or other suitable elastic material. The supporting anti-friction pulleys are placed in the exhaust cavity of the valve, and work upon a prepared pathway made across the exhaust port; otherwise the plate supporting the elastic diaphragm is connected with the segment of a pulley, the circular part of which rests upon a prepared surface in the exhaust port; otherwise, in the case of two valves working back to back, same as in an outside cylinder locomotive engine, the two elastic diaphragms of the valves are connected by a rod passing between the two, the elasticity of the diaphragms allowing for the difference between the movements of the valves, and thus the pressure upon the elastic diaphragm of one valve counterbalances that upon the other valve; otherwise the elastic diaphragm of the valve is connected to a plate or a carriage on the exterior of the valve, which is provided with rollers arranged to work upon a pathway in the valve box on each side of the valve. *Patent abandoned.*

2354. J. EDWARDS. *Improvements in the permanent way of railways.* Dated August 23, 1862.

This invention relates—1, To the making of a continuous sleeper by means of angle or other suitable shape irons, rivetted back to back on to a T-iron, leaving sufficient room between the irons to drop in a double-headed rail, the bottom head resting on the T-iron; a bolt is passed through, which holds the rail in position. 2, The inventor rivets two angle or other shaped irons together, putting a web between. On this iron so prepared he fixes a bridge rail. 3, He places angle or other-shaped irons back to back, and places a web between them; the web is carried above the angle irons, so as to form a stop for the rail, which rail is bolted to this projecting part of the web to hold it in position. 4, He places two angle or other-shaped irons back to back, placing between a web; this web and these angle irons are then rivetted or bolted together, leaving between the angle irons an opening about two inches deep. He then forms a rail of suitable shape, with a feather on one side; this feather drops into the opening left between the angle irons, and is bolted to them. When one head of the rail is worn out, it can be turned on its side, and used in that position, and when the second head is worn out, it can be turned on its other side, and used in that position, thus forming a rail with three heads for running on, thereby effecting great economy. 5, He forms a web of iron, with a suitable hollow and projections in the upper part. Into this hollow he places a suitably-formed rail, which is bolted to the web. This web is very light, and can be turned when one side is worn out, without interfering with the web. 6, He forms a cradle of iron of suitable shape, and into this cradle he drops a double-headed rail, which is bolted to the side of the cradle to hold it in position. 7, He takes a T-iron, and fixes on the top thereof a block of timber, and on the top of this block of timber he fixes a double, single, or bridge rail, using the T-iron as a support. *Patent abandoned.*

2355. F. T. MOISON. *Improvements in the process of cleaning organic matter, and in the machinerg connected therewith.* Dated August 23, 1862.

This invention consists in the treatment of organic matter—more particularly wool and other fibrous materials—charged with fatty and oleaginous or resinous substances, and whereby the inventor separates the said fatty, oleaginous, or resinous substances from such fibrous or other matter. For this purpose, he places the organic matter in a vessel, where it may be subjected to pressure, and he then forces through it—by means of a pump, or by hydrostatic pressure—a current of bi-sulphuret of carbon, or other volatile hydrocarbons, which dissolve the greasy substances, and carry them off with it in a separate receiver, where, by means of heat, he separates the one from the other; and, subsequently, in order to free the organic matter from the volatile oil which may have been absorbed in the mass, he causes it to be traversed by a current of heated air put in motion by a force pump or an ordinary fan. *Patent abandoned.*

2356. J. HINKS and A. DIXON. *Improvements in brooms and brushes, and in the mode of fastening brooms, brushes, and mops to their handles or stules (stuils).* Dated August 23, 1862.

Provisional protection has not been allowed for this invention.

2357. M. K. ANGELO. *Improvements in apparatus used in the manufacture of shellac.* Dated August 23, 1862.

This invention is carried out in the following manner:—The lac or gum is placed in tubes of woven fabric, those which the patentee prefers being woven without any longitudinal seams. He employs metal tubes with gutters or channels at their lower parts, and these metal tubes and gutters are heated externally, and by preference with steam, in a jacket or chamber surrounding the tubes. Through these heated tubes the tubes of woven fabric containing the shellac or gum lac are drawn, whereby the gum as it becomes fluid is caused to filter through the woven fabric, and descends into the gutters of the tubes, the fluid gum being then conducted to and rolled between rollers. The gum in the interior of the woven tubes is prevented passing beyond the lower ends of the heated tubes as the woven tubes are drawn out of such heated tubes by reason of the woven tubes being compressed, and this may be done in any convenient manner; it is, however, preferred to twist them as they progressively come near the end of the heated tubes; or the woven tubes may be drawn over mandrils near the ends of the heated tubes, so as to insure the gum being prevented following with the woven tubes as they pass out of the heated tubes. *Patent completed.*

2358. M. HENRY. *Improvements in stuffing-boxes and their packings.* (A communication.) Dated August 23, 1862.

To simplify the description of this invention, the patentee explains the invention as applied to a piston rod, but it must be understood that it is applied in like manner to valve rods and plunger rods, and other articles or surfaces round which stuffing-boxes and their packings are used. Round the rod are fitted metallic springs or rings. The patentee includes in the term "ring" complete rings, as also springs or pieces of the form of a ring not quite complete, or of a ring cut through, divided, or having a break of continuity at one or more portions of its circumference. Or these rings or springs may be deep rings, or short tubes, or cylinders with or without a longitudinal slit, or division, or break of continuity. The rings may be fitted in grooves or recesses after the manner of piston packing, and they may press on the rod directly, or through the medium of interposed metal rings or segments. Two or more rings may embrace the rod, and be kept to their work by one or more annular or cylindrical springs, which surround the rings, and press on them either directly or through the medium of interposed pieces. In the term "cylindrical" the patentee includes springs of the form of a short cylinder or tube, with a longitudinal slit, division, or break of continuity. This metallic packing takes its fulcrum on the rod or other moving surface round which it is applied, instead of, as in ordinary packing, on the fixed surface of the stuffiing-box or gland. The packing is fitted in a recess or part close to the cylinder-cover or orifice to be packed, that is, as near as possible to the steam or other working fluid. The further part or other end of the stuffing-box or its gland may be extended and fit closely round the rod, to constitute the effective guide for the rod to work through; and by admitting the lubricating material through this part, the rod may be lubricated practically free from contact with the steam or working fluid. *Patent completed.*

2359. C. H. ROECKNER. *Improvements in syphons for discharging or drawing off large bodies of water, and in the mode of charging, fixing, and constructing same, whereby they are rendered perfectly self-acting.* Dated August 23, 1862.

The object and intention of this invention is to dispense with machinery, and simply to employ a steam boiler (which may be portable), or a reservoir containing water, for charging the syphon; and, further, in adapting one or more valves to the legs of the syphon: if two valves, then one of the valves (namely, that by which the water passes out of the syphon into the tidal water course) is so adjusted as to lift outwards, and the other or induction valve lifting inwards. To the extreme upper part or bend of the syphon a pipe is connected, fitted with a cock, for establishing a communication between the exterior of said syphon and an ordinary steam boiler, or it may be a reservoir of water. Now, suppose a syphon thus constructed to be fixed over a coffer dam, for example, one leg thereof being on one side thereof, and the other leg on the opposite side, the former leg being immersed in the water therein, and the outer leg also in water; the inventor proceeds to charge the syphon by admitting steam thereinto from the boiler, or water from a reservoir, thus forming a vacuum in the syphon. He then shuts off the communication between the syphon and the boiler or reservoir, and disconnects the same if desirable. The water now flows out of the syphon by the outlet valve, and continues to do so until the water in the tidal water course reaches the level of the water within the dam; and as the tide rises, the valve prevents the entrance of water into the syphon. In order to avoid the necessity for recharging the syphon periodically, as heretofore practised, he proposes either to form a shallow reservoir beneath and around each leg of the syphon, or to form the ends of the leg turned up so as to contain water, and thus to preserve the vacuum in the syphon. By these means the syphon, when once charged, will continue to work for an indefinite period, and is thus rendered permanently self-acting; moreover, a syphon thus constructed will be found an excellent substitute for a sluice, and infinitely less costly. *Patent abandoned.*

2360. W. E. NEWTON. *Improvements in the mode of and apparatus for treating fermentable substances for brewing and distilling.* (A communication.) Dated August 23, 1862.

One portion of this invention is carried out as follows:—The grain, malt, potatoes, or other substance to be operated upon is soaked for several hours in water, and is afterwards crushed, squeezed, or pressed into a pulpy mass, which is then placed in a vessel, and hot water or steam added until the temperature is raised considerably; or the mass may be heatad by steam pipes until it is converted into a kind of paste. The mass is then passed into a straining apparatus, in which the husks, grains, or unfermentable parts are removed. This removal of the husks and unfermentable particles greatly facilitates the subsequent processes of distilling and brewing, as it economizes heat and prevents the mass from burning. The pulpy mass is then conveyed to a heating apparatus, and the temperature is raised to about 63 deg. of Reaumur, at which temperature sugar begins to form. Here it remains for a certain time, and it is then cooled by passing cold water through it, after which it is passed into the fermenting tubs. The above is the process to be followed for distilling. *Patent completed.*

2361. M. J. HAINES. *Improvements in the manufacture of driving bands or straps.* Dated August 25, 1862.

In the specification of an invention for which provisonal protection was granted to the present pateutee on the 21st August, 1860 (No. 2078), was described the manufacture of driving straps of small strips of leather, hide, or other suitable material, cut to a width equal to the thickness, and to a length equal to the width of the intended strap. The strips had holes formed through them, and were threaded, side by side, on lengths of wire rope, the wire rope thus running longitudinally of the strap. Now, according to the present invention, the patentee binds round the lengths of wire rope with a helical coil of wire, in such manner that the coils lie close up to one another, before threading the strips of hide, or other material upon them, or, in place of employing wire rope thus bound round with wire, straight lengths of wire bound round with a helical coil of wire may be employed. *Patent completed.*

2362. H. R. HUGHES. *Improvements in the construction of sawing machines.* Dated August 26, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2363. W. E. GEDGE. *Improvements in stays or corsets.* (A communication.) Dated August 26, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2364. J. and B. HARRISON. *Improvements in clod crushers.* Dated August 26, 1862.

This invention consists in the use of two, three, four, or more drums, wheels, or discs placed at intervals on a shaft, and a series of bars or lags with spikes cast or fixed on one side thereof, and which bars are fixed at small distances apart, or leaving spaces betwixt them across the edges of the drums with the spikes outward, thereby constituting a spiked skeleton roller or clod-crusher. The bars are formed to fit into dovetailed notches in the drums or discs, and arranged so that the spikes on one bar shall be intermediate to those on the adjoining bars in the line or direction of rotation. *Patent completed.*

2365. G. DAVIES. *Improved machines for washing skeins of cotton, linen, wool, or silk.* (A communication.) Dated August 26, 1862.

These machines are applicable as portable machines, or they may be fixed on a water-course with either a constant or variable level. When intended to be used in the workshop, and not fixed on a water-course, the machine is constructed as follows:—Upon a cistern or vessel having an inclined bottom of either metal or wood (and furnished at its upper end with a compartment to contain the feed water, and at the opposite end with two sluices for the ejection of the same) is fixed the framing of the machine, supporting a sliding cross-beam carrying a suitable number of bobbins, upon which bobbins the skeins are placed in such a manner that their lower part or loop hangs in the water of the cistern. The bobbins are caused to revolve continuously by means of an endless belt passing over a pulley actuated by means of a worm and wheel, and bevel gearing driven by the main or crank shaft, at the same time that the cross-beam which carries them is caused to slide to and fro by means of a connecting rod driven by a crank on the said shaft, and thus a compound movement, similar to that used in hand washing, is imparted to the skeins. The pin of the crank above named is so constructed as to be capable of sliding on the crank, so that the amount of movement given to the cross-beam may be readily adjusted. The whole machine is driven by the direct application of a small steam engine to the crank shaft. *Patent completed.*

PROVISIONAL PROTECTIONS.

Dated Dec. 10, 1862.

3315. W. Clark, 53, Chancery-lane, engineer. Improvements in umbrellas. (A communication.)

Dated Dec. 16, 1862.

3354. J. Farley, Bolton-le-Moors, engineer, and J. Crowther, Bradford, York, carrier. Certain improvements in steam engines and apparatus connected therewith.

Dated Feb. 9, 1863.

356. J. Mackintosh, North-bank, Regent's-park. Improvements in obtaining and applying motive power.

Dated Feb. 14, 1863.

411. F. E. Walker, James's-terrace, Waterloo-road, gunmaker. Improvements in the construction of breech-loading firearms.

Dated Feb. 20, 1863.

460. W. Marsden, 49, Old Bailey. Improvements in envelopes.

Dated Feb. 25, 1863.

528. T. V. Lee, 6, Bank-chambers, Lothbury, civil engineer. Improvements in machinery for digging, compressing, and moulding peat or turf, and for retorts and kilns for drying peat or turf, and making peat or turf charcoal through the agency of hydro-caloric or superheated steam, and for collecting the products of distillation whilst charring the peat or turf.

532. J. Inglis, Edinburgh, bookbinder. Improvements in machinery or apparatus for folding paper and othor fabrics or materials.

PATENTS APPLIED FOR WITH COMPLETE SPECIFICATIONS.

Dated March 4, 1863.

608. P. Adie, Strand, mathematical instrument maker.

Improvements in means and apparatus for measuring angular and actual distances.

Dated March 9, 1863.

658. J. H. Johnson, 47, Lincoln's-inn-fields, gentleman. Improvements in the treatment of certain fibrous vegetable substances with a view to the production of textile materials therefrom. (A communication.)

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

From the *London Gazette*, March 17, 1863.

2966. F. Trachsel and T. Clayton. Obtaining light, heat, and ventilation.
2983. T. Huntley. Cooking and bath-heating apparatuses.

NOTE.—Specifications will be forwarded by post from the Great Seal Patent Office (publishing department) on receipt of the amount of price and postage. Sums exceeding 5s. must be remitted by Post Office Order, made payable at the Post Office, High Holborn, to Mr. Bennet Woodcroft, Great Seal Patent Office, 25, Southampton-buildings, Chancery-lane.

The *Art-Journal* of November, in its description of Benson's Great Clock, says: "It has attracted universal attention, its construction has, we believe, obtained general and strong approval, it is one of the largest chiming clocks as yet manufactured in this country." Benson's new show rooms contain clocks designed by the first artists of the day, and include clocks for the drawing room, dining room, bed room, library, hall, staircase, bracket, carriage, church, turret, railways, warehouse, counting house; with musical, astronomical and every description of clock, from the plainest to the highest quality of which the art is at present capable. Church and turret clocks specially estimated for. Benson's illustrated phamphlet on clocks and watches (free by post for two stamps), contains a short history of clock and watch-making, with descriptions and prices; it acts as a guide in the purchase of a clock or watch, and enables those who live in Scotland, Ireland, Wales, the Colonies, India, or any part of the world to select a clock. J. W. Benson received a Prize Medal and honourable mention.—33 and 34, Ludgate-hill. Established 1749.

◆

LONDON, FRIDAY, MARCH 27, 1863.

POLITICAL ECONOMISTS AND PATENT RIGHT.

When a man's mind is soaring in the higher flights of science or philosophy, it has a proverbially-known tendency to ignore the earth below, with its material obstacles—its human passions and frailties; and thus the philosopher, while gazing on the unapproachable stars, often stumbles into the muddy ditch. If the theoretical mechanician disregards practical considerations while designing a machine, he produces a thing that will not work. When a general forgets the requirements of his soldiers' stomachs and legs, he is sure to be beaten by a more practical adversary. Should a Plato-like statesman try to enforce a Model Republic, while ignoring Napoleon's dictum, "que c'est le ventre qui fait les revolutions," he will either be hurled from power, or he will ruin his country. Last of all, and this instance is our case in point, when "political economists" wish to make and unmake laws, of the working of which they can take but a bird's-eye view, they are sure to fail most egregiously; as human society is not founded on an ethereal basis of abstract and absolute principles, but rather on the actual realities of mundane existence.

Too often does it also happen that the most powerful minds are influenced by crotchets, particularly when estimating the very things to which they have given the attention of a lifetime. Thus Shakespeare had a weakness for making very bad puns, and Wellington was to the last the gallant and obstinate protector of old "Brown Bess."

These reflections naturally arise in one's mind at the sight of the organized opposition in some of the higher scientific circles, both in England and France, to Patent Right. We find with great astonishment that Monsieur Michel Chevalier, the well-known French political economist, in his introduction to the French Reports of the International Jury of the London Exhibition of 1862, expresses himself in favour of the abolition of Patent Right, and proposes an unworkable plan as a substitute. The Professor of Political Economy in the University of Oxford, the Rev. J. E. T. Rogers, lately read a Paper "On the Rationale and Working of the Patent Laws" before the Statistical Society, in which he expressed somewhat similar opinions to those ennunciated by Monsieur Michel Chevalier, but with some variations that we will indicate further on. The differences are certainly in favour of Mr. Rogers's superior ingenuousness, as many of his objections to patent right could be answered by the counter-arguments he himself, consciously or unconsciously, adduces. Professor Rogers stated that patents are evidently a branch of the ancient and odious system of monopolies, so notorious during the reign of James I. Not that, continued the Professor, all monopolies are necessarily mischievous; the paper-money monopoly of the Bank of England being generally held as advantageous to the public.

A bad origin is evidently no argument against any law; and the entire political constitution peculiar to England has mainly resulted from an organized system of gradually eliminating abuses. Not merely in the reign of James I., but previously, during the time of Queen Elizabeth, there were great complaints made as to then existing monopolies of almost every branch of trade and manufacture, such as salt, vinegar, oil, &c. Even then, however, men of discernment saw and acknowledged the great differences between such oppressive privileges, and those granted for new inventions and discoveries. The great Bacon, then Attorney-General, in a famous debate in the House of Commons concerning monopolies, 20th November, 1601 (reign of Elizabeth), in the course of his speech, very thoroughly defines the difference as follows:—"If any man out of his own wit or industry finds out anything beneficial for the commonwealth, or brings in any new invention, which every subject of this kingdon may use, yet in regard of his pains and travail therein, Her Majesty perhaps is pleased to grant him a privilege to use the same, only by himself or his deputies, for a certain time; this is one kind of monopoly."

M. Michel Chevalier asks the questions: Is a patent for an invention founded on a basis of positive right? Does an invention in the manufacturing arts afford the character of ownership in a determinate manner? Is it a thing that a man can claim to the exclusion of others, that is to say, can appropriate to himself, even for a duration limited to only fifteen years?

Mr. Rogers observed that property, as defined by economists, must be capable of appropriation, division, limitation, and identification. It does not, however, follow, continues Mr. Rogers, that all property is necessarily of a material description. A man's character, the debts due to him, his trade mark, his signature to a cheque, (and, we would add, his invention), were allowed by the learned Professor as coming within the definition of property.

As to the abstract right of an originator to his original idea, there never appeared to us that there could be the slightest doubt in the matter. What is more free than thought; and what thing can be more essentially the property of a man than the emanation of his brain?—what can be more determinately the property of a creator than the object he has created? What other property can be so easily hoarded away, or taken out of the country, or even carried with its possessor to the grave? The inventor says to society: "I have an improvement that will increase the present means of production; give me an exclusive right to use it for a limited period, in order that I may be remunerated for the time and energies I have spent to enable me to make this discovery, and the time and the energies I must still exercise before I can make my discovery available. Your entire, complete, and perpetual possession of my idea will merely be deferred for a short period." Mr. Rogers asserts, however, that the inventor's bargain with the public is entirely one-sided; that he keeps his own secret if he thinks it his own interest to do so, but demands a monopoly in his discovery if he thinks it desirable to communicate it to the public. As far as we understand Mr. Rogers, it appears to us that he is ignorant of the practical patent law, as it at present exists. A patent is completely invalid if a patentee in his specification in the least attempts to mislead the public as to the nature of his invention, or even if the invention be insufficiently described. The bargain between society and the inventor is nullified if the patentee does not completely fulfil the contract. Mr. Rogers further demurs to the contract between society and the inventor, on the plea that, "No one can call that a fair bargain which is involuntary on one side and voluntary on another." We cannot conceive a more childish train of reasoning. If society does not want the patented invention, the patentee cannot force the public to use it, just as the writer of a dull book cannot force the public to buy and read his effusions. The patentee can with as little reason demand a royalty as the author can demand the purchase of his work. If an inventor chooses to keep his idea a secret, and does not take out a patent (as is sometimes done from the present unsatisfactory state of the law), what right has the public to demand a revelation of the secret? The right of the strongest? But that right could only exist by an annihilation of all right, and a return to the good old days of—

> "They shall take who have the power,
> And they shall keep who can."

We would remind Mr. Rogers of another University man, an intellect of a very different calibre to his own, Dr. Wollaston. That famous chemist discovered a particular mode of preparing malleable platinum; he practised this process in secret for many years, and realized a large sum of money by it. The Doctor only disclosed the process on his deathbed, and probably described it only incompletely.

Mr. Rogers believes that "material inventions are either the result of a sudden conception, or of the elaboration of well-known and general laws;" and Monsieur Arthur Legrand, another of the writers in the French Jurors' Reports on the Exhibition, says: "Each year, each generation, brings with itself a tribute of novelties, that at a given instant are translated into practice with a kind of spontaneousness *(spontanéité)* when the time is come—that is to say, when a demand has made itself felt. Each thing is thus divulged according to its own time by the natural effect of a want born, as it were, out of the progress acquired by science and industry. One could even add, that he who makes a discovery is merely the particular instrument of the generation to which he belongs, and that his century, rather than himself, deserves the title of inventor."

This elaborate theory of the fire of genius being a kind of spontaneous combustion, is very remarkable. How is it, that, if an invention be such an easy matter to make, being merely "the result of a sudden conception, or the elaboration of well-known and general natural laws," that Professor Rogers himself has never made an invention? He has not even brought a new argument to bear against patents, his paper being merely an industrious compilation of objections that have been made long ago. Why has not Monsieur Arthur Legrand made himself, "l'instrument de la génération à laquelle il appartient." Is it for the same reason that even mushrooms require a particular kind of soil and favourable circumstances for their "spontaneous generation"? We utterly deny, and we appeal to all scientific history to disprove the assertion, that the century has always distinctly put the questions for the solution of inventors. Whenever a really original patent is taken out, we certainly see that it suggests a host of plagiarisms; but that is scarcely what M. Arthur Legrand means.

In a similar strain M. Michel Chevalier says, page 166:—"The fact is, that there is at present a common and almost inexhaustible fund of notions applicable to industry, and that almost always, when the want of any new process is once felt, there is reason to suppose that ten persons, instead of one, will make the necessary discovery, and at about the same time." Such assertions show either utter ignorance as to technical matters, or complete oblivion as to the many requirements of the manufacturing arts, on the part of Monsieur Michel Chevalier, Monsieur Arthur Legrand, and Professor Rogers. To merely give a few instances at random: How is it that no sufficient means yet exist for preventing accidents on railways and in mines? Why is there yet no complete arrangement for getting an exact number of revolutions from an engine driving machinery for spinning fine numbers? How is it that for more than twenty-five years we have burnt coke instead of coal, and thus wasted millions' worth of fuel in our locomotive fire-boxes? A good and simple boiler feed-apparatus was always a desideratum, but Giffard's injector was only brought out a few years ago, after boilers had been in use for more than a century. Why is there no good means of preventing the unequal wear of the cylinder of a horizontal engine? Any practical man could instantly jot down a number of additional similar problems still pending for a solution; but we will ask, how is it that some five or six hundred inventors (as proved by the Patent Indices) have to try their hands at any really great mechanical or chemical questions before it is solved?

Mr. Michel Chevalier says:—"If I invent any mechanism to-day, another man may invent the same thing to-morrow, and more; nothing proves that another did not invent it yesterday." In a somewhat similar way, Professor Rogers says:—"The law grants a monopoly to the first applicant; but by a perfectly independent train of thought, or application of labour, another person may have discovered the same thing; but the privilege is bestowed upon the first to ask for it." To these dicta we would reply, that it very seldom happens, unless there be a plagiarism, that two mechanical arrangements to produce the same effect, are exactly similar. It does certainly occur that very similar patents are sometimes taken out during the six months' provisional protection, and this forms one of the objections to that clause of the law. We have, however, noticed that this clashing of invention generally takes place when a previous successful patent has urged upon people whose trade it threatens the necessity of evading or superseding the invention.

In any case, where is the harm of granting a patent to the man who has first brought the invention to maturity? Should the plate and the stakes be refused to the swiftest horse? "First come first served," is a homely dictum; but it is of universal application; and a quarter of an hour will decide the result of a battle, or will settle for ever the destinies of a nation. Ought we to refuse to an ingenious and active man the reward for his improved process, because another man behind him is blundering and procrastinating with a similar idea?

Mr. Rogers states that he does not wish to abolish copyright, inasmuch as, though two persons could invent the same thing, it was impossible two persons could write independently the same book. We are surprised that Mr. Rogers, who must know something of the Doctrine of Chances, could make such a shallow objection; for there would certainly be very little likelihood of two books being written in precisely the same words; not so, however, as to the ideas, as any one can see that precisely similar views are often enunciated in works that have been simultaneously published. It may be objected in favour of copyright, as against patent right, that the former does not prevent the publishing of a book containing similar ideas differently expressed. This, however, is only the case with some kinds of books; and it is also notorious that many patents embody the main idea of a previous invention, while evading the law by adopting different, and sometimes superior means, to carry out the original idea. A patent does not cover a principle, and copyright does not protect the main idea of a book from plagiarism.

We further find in the French Report:—"Nineteen times in twenty, or ninety-nine times in a hundred, the labours of *savants* have furnished the basis of inventions in the manufactures and the substance of the patents. *Savants* abstain from taking out patents for their scientific discoveries. The text of the French law is such that they could not found valid patents on these discoveries. Therefore, if those who have the principal share in inventing are excluded from the profits to be acquired by the possession of inventions, how can others base a right to claim them as their exclusive property?" Any one can see by the lists of the some eight thousand English and French patents that are annually taken out, that but a small proportion of these patented inventions can be said to trace their origin from the studies or laboratories of purely scientific men; certainly not to the extent of 99 per cent.; in fact, we should be inclined to assert that the relative proportion was exactly the reverse. In any case, the man of pure science is rewarded by the honours and respect that generally attend scientific eminence, even when unaccompanied by wealth. To render practicable most scientific discoveries, and to bring them into the market, generally requires different aptitudes to those exercised in making a scientific discovery. The men of pure science, however, have not been always indifferent to the blandishments of patent right. We can cite Sir David Brewster and his patent kaleidoscope, Liebig and his manure, and other patents, Schönbein and his patented gun-cotton, &c. Gay Lussac patented several of his discoveries, among which was the famous patent for separating the stearine from the ealine of tallow. The noble-minded Arago has often strenuously and with great eloquence defended the right of a scientific discoverer to patent the result of his labours. It has been whispered that no less a man than Faraday, being prevented by the existing etiquette among men of science from patenting some discoveries in gas lighting, permitted his brother to take out the patents. We might multiply these instances; and, at any rate, it will be seen that it is a mere matter of choice with any experimental philosopher to patent his discoveries before divulging them to the world.

Mr. Rogers seemed to believe that the stimulus of self-interest is required to urge on invention; but he very properly rejected as impracticable the proposal to institute a Board for awarding prizes to such inventions as might be thought of public utility. Not so M. Michel Chevalier, for this gentleman proposes (*Exposition Universelle de Londres*, tome 1, Introduction, page 167), "to reward by a special gift (*dotation speciale*) any ingenious man who, after a certain time of trial, should have rendered signal service to society by any discovery. This has been the way adopted in France, with regard to the inventors of photography." With playful irony it is added:—"These recompences would not ruin the public treasury; there would be no necessity to award them very often." We certainly thought that the Utopian theory of bounties to inventors had long been exploded, even in the "higher regions" of political economy.

If the investigations of such a Board of Examiners be secret, it would be difficult for the public to believe in the impartiality of the awards. A public tribunal of merit would be a daily and hourly arena for the gladiatorial combats of rival inventors. How could such a Board be constituted? Upon what principles could its decisions be based? If merely the utility of the invention be taken into consideration, must valuable discoveries resulting from chance or a fortunate inspiration be excluded from competition for the bounty? As Butler in his "Hudibras" says, with some truth and more wit:—

> "All the inventions that the world contains
> Were not by reason first found out, nor brains;
> But pass for theirs who had the luck to light
> Upon them by mistake or oversight."

Should the merit of the inventor himself be taken as a criterion, and the fact be considered at a money value, of a man having spent his fortune and his lifetime in the realization of an invention of perhaps less utility than another discovery; the result of a fortuitous observation or of a sudden inspiration?

M. Michel Chevalier cites the reward given by the French Government to Daguerre, the inventor of daguerreotyping. This grand reward for a really magnificent discovery consisted in a paltry life annuity of £250 (6,000 francs). By a curious coincidence the same instance was cited against patent law in the Report of the Jury on Philosophical Instruments exhibited at the Exhibition of 1851. (See "Reports by the Juries on the Exhibition of 1851," Class X., page 246.) "The great advance of photography is chiefly due to the avoidance of patents in connection with its improvement." Monsieur Michel Chevalier, and the learned jurors of Class X., could scarcely have chosen a more unfortunate "modern instance" for deducing their "lame and impotent conclusions." The discovery of Daguerre dates from 1839; but, previously to this, in 1834, Mr. W. H. Fox Talbot had invented the means of fixing the images of the camera obscura on paper. This discovery was almost neglected till 1847. Mr. William Henry Fox Talbot took out no less than five patents for discoveries connected with photography. His first patent was described in the Mechanics' Magazine, Vol. 35, page 188, and, as they came out, his other patents were described. The English patent of Daguerre (No. 8194, dated 1839) was bought for £1,600; it was thus still valid in 1853. Photography, nevertheless, did not take its rise in France, where Daguerre's patent was public property, but in England, where the patent still existed. Photography only appeared in France in 1847, twelve years after the discovery of Daguerre, and, besides, the improvements made in France in the processes of photography did not originate with the public, but with Monsieur Niépce, the successor of his uncle, M. Nicéphorus Niépce, one of the originators of sun-painting.*

It is simply incorrect to state that patents have been avoided in connection with the improvement of photography. More than 200 patents have been taken out for inventions and improvements in the photographic arts and in the use of the stereoscope in England alone. There are always a greater number of patents annually taken out in France than in England.

Mr. Rogers stated that it was difficult to decide whether the Patent Laws were or were not a stimulus to invention; as they had always existed in this country it is impossible to say what we should have done without them. We may add that the only civilized country in the world still without a patent law is Switzerland. The probable reason that Switzerland has no such laws consists in the fact that this country is divided into Federative Cantons, constantly disputing with each other. A patent for a single Canton would, of course, be no protection.

---

* Monsieur Nicéphorus Niépce, in December, 1827, submitted some pictures taken upon silvered copper plates smeared with the bitumen of Judaea to the Royal Society, having, as early as 1814, made experiments to fix the images produced in the camera obscura. Daguerre's English patent is taken out in the name of Miles Berry, as a communication from himself and J. I. Niépce, jun.

Mr. Rogers cited the civil engineer, the late I. K. Brunel, as being an opponent of patents. The late Mr. Brunel's father, M. I. Brunel, who was more of a mechanical engineer, was in favour of Patent Right. Indeed, we consider it to be a noticeable fact that several civil engineers in successful practice are averse to patents. We might cite Mr. John Scott Russell, Sir William Armstrong, and the late Messrs. Cubitt and John Meadows Rendel, although nearly all of these gentlemen greatly owed their rise in life to successful patents. The reason of this opposition seems very obvious to us. Being in possession of a large and varied practice, and often requiring separate mechanical details for each particular undertaking, it was natural that the arrangements they adopted should sometimes clash with already existing patents. It is painful to have to pay a royalty for a mechanical detail that might have been invented by a man's own self. A thing looks so easy to achieve when it is once done !

Thus behind the well-meaning band of desk-philosophers, pioneering the way for a clean sweep of patent right, there is a serried phalanx of men who see that it would be for their own interest to abolish these rights—a band of men who would like to swell their incomes by gratuitously appropriating the results of other men's labours, and would look upon the stagnation of invention as a safeguard against a depreciation of their manufacturing plant.

II.

ENGINEERING LITERATURE.

A practical little pamphlet* on the forging, hardening, tempering, expansion, annealing, and shrinking of steel has been just issued; and it well deserves the attention of any apprentice, or even workman, wishing for additional information on such an important branch of workshop experience. The little book is evidently written by a good workman for the use of workmen; and although defaced by some faults of grammar and style, it is nevertheless clear and precise. Of course mere reading can never teach a man to file straight, or to forge and temper a chisel; nevertheless, the aid that books can afford is no more to be despised than good advice is to be contemned. The work contains, step by step, practical directions upon the forging, hardening, and tempering of steel chisels for turners, &c. The title is rather a misnomer; the scientific theories as to the formation, chemical constituents, &c., of steel are now being so much discussed and so often patented, that the title, "The Management of Steel," would lead us to expect a latent puff of some newly-patented process.

To those delighting in ingenious and novel combinations of mechanical motions, a good compilation of the greater part of the movements known must always be valuable and interesting. A work describing five hundred of the known mechanical movements, illustrated by sixteen large lithographed plates and several woodcuts, has been lately published by Mr. Joseph Willcock, Mem.Soc.Eng. Such a book must necessarily be mainly a compilation, and thus the main French and English sources of the book we have examined are the "Practical Mechanic and Engineers' Magazine (1842 and 1843)," Willis's "Principles of Mechanism," Olinthus Gregory's "Treatise on Mechanics," Delauncey's "Cours Elémentaire de Mécanique Thèorique et Appliquée," Buchanan's "Essays on Millwork," White's "Century of Inventions," "Bulletin de la Societé Industrielle de Mulhouse," &c. The author begins by describing the parallel motions, and he then gives the escapement, intermittent, and the movements by means of pulleys and bands. The teeth pitches, and the making of wheel-patterns, are treated on very completely. The circular motions, and their changes into rectilinear movements, as well as the differential and some miscellaneous movements, epicyclic trains, &c., then follow. A very complete collection of the movements used in gas apparatus is then given; and following these, a collection of various hydraulic and pneumatic apparatus, and of the lathe chucks manufactured by Messrs. Holtzapfel and Co. Some of the plates of diagrams are very well lithographed. We miss some well-known motions; amongst others, Watt's sun-and-planet motion; and, to take a more modern instance, the quick-return motion used by Mr. Whitworth in his shaping machines. These and others could, however, be added by a possessor of the work; and an industrious student of engineering could thus, with the addition of manuscript notes, in course of time make this book a foundation for a unique and very valuable collection of mechanical movements.

II.

INSTITUTION OF CIVIL ENGINEERS.

At the meeting of the Institution of Civil Engineers on February 17, a discussion upon the two Papers, "On the Drainage of Dundee," by Mr. J. Fulton, and "On the Sewerage of Newport, Monmouthshire," by Mr. A. Williams, Assoc. Inst. C.E., F.G.S. (which will be found reported in the Mechanics' Magazine of Feb. 13), occupied the whole of the evening.

It was remarked that, although the author of the first paper had stated that no ventilation whatever had been applied to the sewers in Dundee, yet, with apparent inconsistency, he spoke of the gases of the sewers being prevented from escaping into the streets and houses by trapped gullies. It was urged that it was dangerous to lay down a system of sewers over an entire town, without in the first place providing, as part of the scheme, for the fullest and freest ventilation, particularly at the higher levels; and that care was specially necessary in towns presenting naturally steep gradients. Disease had broken out in well-sewered districts, which was traced to the connection of the house drains with unventilated sewers; the highest portions of the town suffering most severely. If the sewers of Dundee were sweet, it would lead to the inference that they must have been badly constructed, and that there were joints and crevices which let out the gases; for with a perfectly tight sewer, the gases must rise to the upper extremity, and escape into the houses through the house drains.

It was thought that the sections of the Newport sewers were of the most approved forms, and that the bricks employed there were admirably adapted for the construction of such sewers with economy. But it was contended that there was no advantage in building brick sewers sufficiently large for a man to pass through, unless those dimensions were required to discharge the sewage flowing into them. In every instance where there were two rings of brickwork in the invert, there should be two rows of "headers" at or about the springing, so as to bond and tie the work together where the arch commenced.

In a hilly town the whole system of sewers should not be so connected together as to allow of the accumulation of the sewage gases in the higher parts of the district. Where the gradient was steeper than 1 in 200, and a sewer was one mile in length, it should be divided by steps or falls, and there should be a flap valve upon the upper or discharging end of the sewer, and at least two street grates at this point, so as to ensure thorough ventilation. Where the sewage was discharged into a river, having a low summer level and a high flood level, it was not always practicable, or desirable, to carry the whole of the sewage in flood down below the summer level. In such cases the arrangement adopted at Windsor Castle might be followed. Formerly a large brick sewer discharged itself into the Thames, close to the Queen's private walk, and was a source of nuisance. By fixing a cast-iron pipe at the bottom of the sewer, and putting a slight dam in front of the junction, all the ordinary sewage was discharged by the iron pipe below the summer level. The brick sewer took away all the storm waters, which could be passed into the river with impunity, as they would be in extreme dilution, and the river itself would be in flood.

It was stated that the invert of the main outlet sewer at West Ham, which was 4 ft. 6 in. in height by 4 ft. in width, was laid for about half-a-mile at the level of low water of spring tides, and then for 2½ miles with a fall of 3 ft. per mile. The surface of the ground was from 10 ft. to 12 ft. below high water in the Thames, and the subsoil was so porous, that when the trench was excavated the water could not be pumped below a certain level. A cast-iron invert was therefore devised, and upon it cement blocks were laid to above the water line; the other portions of the sewer being built in the ordinary way. About three miles of that sewer had been in use for nearly two years, and no difficulty was found in keeping it clean, although the velocity of discharge was mainly that due to the surface gradient, or head.

As the question of town sewerage was of daily increasing importance, the principles which should be adopted might be briefly stated. Every sewer should be straight from point to point, and at every change either in the line or the gradient, there should be a manhole or a lamp-hole, affording means of access to the sewer, as well as providing ventilation. A cesspit should be formed at the side of each of these ventilating shafts, to catch the detritus from the roads; and the gully grate and entrance should be over it, and not directly above the crown of the sewer, as was the case in some parts of the metropolis. Between the side chamber and the shaft charcoal filters should be fixed, so as to deodorize the foul gases before passing into the streets. Sewers of unequal dimensions should never be level at the inverts; it was safer, as a rule, that they should meet at the crown. In the former case, the larger sewer would dam back the sewage in the smaller tributary, and prevents its being flushed out. At Carlisle the main sewer had a fall of 1 in 700 for a mile and a quarter. It was frequently liable to be flooded, and at times the water line was from 18 feet to 20 feet above the level of the invert. That sewer had been in operation for six or seven years without requiring any outlay for cleansing. At every manhole there was a groove in the brickwork to receive a stop-plank, by which the sewers could be flushed out in sections, either by accumulated sewerage, or by the admission of water from the water works.

The fouling of rivers, by allowing undiluted sewage to pass into the nearest available water courses, was a question of serious importance. It was believed that the cheapest element to remove soil refuse was water, and that the readiest method was by a proper system of sewers. If it was not worth while commercially to pump the fluids and solids, for the purpose of appropriating them to agricultural uses, then the solids should be removed by deposition and filtration, and the liquids be deodorized, before entering the rivers and water courses. The land was the proper place to which the soil refuse should go, and if the authorities of a town could not dispose of it at a profit, they ought to be compelled to incur the necessary expenditure for carrying it to some place where it could be beneficially applied, without creating a nuisance.

---

* On the Management of Steel. By George Ede. London: W. Tweedie, 337, Strand. 1s.

It was remarked that, the sewers on the south side of the River Thames were all provided with ventilators, having side-pits which prevented stones and mud from entering the sewers. In confirmation of the statement, as to the advantage of a supplementary pipe outlet to discharge at low water, it was mentioned that a similar arrangement had been carried out at Battersea eight or ten years ago, and subsequently at four or five other outlets of the main sewers on the south side of the River Thames. With reference to the question of cleansing sewers, it was thought that the method adopted at Dundee was complicated and expensive; and that if a greater fall had been given to the sewers, and a supply of water had been obtained occasionally, as required, from the water company, both the first cost of the works, and the working expenses, would have been reduced. The plan pursued in the metropolis was simpler and cheaper. In the pipe or sewer a valve was fixed, which could be kept closed until a head of water accumulated; when this valve was opened, the rush of water cleared away any deposit, including macadamised matter and stones.

It was contended that no system was perfect which permitted accumulations in the sewers; for if the velocity of the flowing sewage was insufficient to prevent the deposit of sand, grit, or other insoluble substances, such matter ought not to be allowed to enter the sewers, and by suitable gully traps this could be easily prevented. Street gullies should be so constructed as to prevent the entering of road detritus into the sewers, and to arrest the escape of noxious effluvia, while at the same time they should provide for the admission of a downward current of air, to aid in the ventilation of the sewer. With reference to the direction of the air passing through sewers, experiments showed, that it was sometimes with and sometimes against the sewage flow, and that it was not governed either by the velocity, or the temperature, or the direction of the sewage, but appeared to be determined by the various points of ingress and egress, and by the number of gullies and ventilating shafts.

There was still a diversity of opinion as to the proper size of sewers; but it was believed that, in ordinary town districts, calculating upon a maximum fall of rain of one inch in half-an-hour, and that it all passed directly into the sewers, the following proportions would prevent silting, if the district was thickly populated, and the house drains were connected with the sewer:—

Diameter of Sewer.	Inclination.	Drainage Area.
Inches.		Square Feet.
6	1 in 50	200
9	1 in 100	400
12	1 in 150	650
15	1 in 200	1,000
18	1 in 250	1,400
21	1 in 300	1,800

To this it was replied, that no specific rules could be laid down which would apply to every town in the United Kingdom, each of which must be dealt with according to the local circumstances and peculiarities of the case. The character of the outlet, the rate of inclination and the nature of the surface of the ground, the rate and amount of the rainfall, the number of houses draining into the sewers, the extent of the population, and other things, all required consideration.

The extension of the main sewerage works of the city of New York, under the administration of the Croton Aqueduct Department, was alluded to, as affording an illustration of the application, to a particular case, of the results arrived at, after the consideration of the facts and arguments which had some years ago been elicited by what was popularly known as the "small-pipe controversy." The material adopted was brick, set dry, or in hydraulic cement, as the circumstances of the locality required; and the cross section was an egg-shape. In determining the sizes of the sewers, the Croton Aqueduct Department assumed that the maximum rainfall on Manhattan Island never exceeded one inch in an hour, and the capacities of the several main sewers were adjusted to provide for that amount, in addition to the maximum prospective house sewage flow of the several districts to be drained. As the streets of the modern part of New York were laid down in right lines—right lines with confluent junctions were adopted for the sewers. The bottoms of the sewers were also, as far as practicable, constructed on uniform gradients; but level lines for the bottom of sewers were considered objectionable, as decreasing the hydraulic mean depth of the sewer at the outlet, where it was most needed. Receiving basins for the road detritus, with connecting culverts for passing the water into the sewers, were erected at the corners of the streets, and in other suitable localities, and it was stated that these arrangements were found sufficient to keep the sewers free from any permanent deposit.

In reply upon the discussion it was remarked that, at Newport, the cost of a brick sewer 14 in. diameter, at a depth of 10 ft., was only 7s. 7d. per lineal yard, including junction pipes for house drains, and that in the same locality the cost of a pipe sewer 12 in. diameter would have been as much, if not more. Brick sewers sufficiently large for a man to pass through, had also been built there for 11s. per lineal yard, whilst at Dundee the average prices were stated to have been for tubular drains 13s., and for brick sewers 33s. per lineal yard.

In conclusion, the necessity for the thorough ventilation of sewers was insisted on; and as the only way to render sewer gases innocuous was by a large admixture of atmospheric air, there should be frequent inlets for the admission of air, as well as numerous outlets for the escape of the foul gases. With regard to the fouling of rivers, no doubt by vastly increasing the local burdens upon trade and manufacture, means might be provided for depositing the heavy matters, and for deodorizing and disinfecting the fluid portions of sewage; but such nuisances were, to some extent, the penalty incurred for concentrating the population in dense masses, and it was hopeless to expect, that the rivers in the neighbourhood of large manufacturing towns could ever be restored to the former clearness.

March 24, 1863, John Hawkshaw, Esq., president, in the chair. The first Paper read was "Description of the Lydgate and of the Buckhorn Weston Railway Tunnels," by Mr. J. G. Fraser, M. Inst. C.E.

It was assumed, that the aggregate length of the tunnels now daily traversed by railway trains in the United Kingdom amounted to 80 miles; and supposing their cost to have been on an average £45 per lineal yard, their construction must have caused the expenditure of six and a half millions sterling. Up to the present time this interesting branch of Civil Engineering had not been much discussed at the Institution; as the Minutes of Proceedings only contained accounts of a total length of about three miles, involving an outlay of about one quarter of a million sterling. Each tunnel had its own history, and its construction demanded peculiar treatment, according to the character of the strata, the springs of water, &c. If particulars of these works were transmitted to the Institution from time to time, more effectual measures might in many cases be practised, with advantage to public economy.

The tunnels forming the subject of this communication were both executed under the immediate superintendence of the author, as resident engineer for Messrs. Locke and Errington, the engineers-in-chief.

The Lydgate Tunnel, on the Oldham branch of the London and North Western Railway, was driven through the coal measures. A longitudinal section which accompanied the Paper, prepared from actual measurements taken during the progress of the works, illustrated the geological details. Faults were common in this formation: sometimes severing it in the line of the dip, and at others in the line of the bearing. Several distortions were encountered, and at one point, one-half of the tunnel was in shale and rock, and the other half in wet and loose shale. The total length of the tunnel was 1,332 lineal yards; of this about 1,046 yards were on a straight line, and 286 yards on a curve of 74 chains radius; its width was 25 ft. at the level of the rails, with a height of 20 ft. Four permanent shafts, each 9 ft. in diameter in the clear, were sunk at intervals of about 230 yds., of the respective depths of 53½, 80, 75¼, and 53 yds. They were lined with 9-in. brickwork, or with 12 in. of masonry, except in the rock. An old colliery shaft, which had been closed for many years, was also re-opened, and a cross-heading was driven from it into the tunnel, a distance of 13½ yds. When foul air was met with, a supply of fresh air was forced into the workings by means of fans until a junction was effected between the headings. There was a considerable amount of choke-damp in the neighbourhood of the old coal workings. To overcome its effects, a bore-hole was sunk from the surface, which was lined with an iron pipe, and through this fresh air was forced into the tunnel. The sinking of the shafts was carried on in the usual manner, by excavating through soft material, and by blasting and drilling through rock. The average rate of progress was 11 lineal yards per month. After attaining a depth of 20 yards, the material was raised by engine power.

A bottom heading was driven from the faces worked from the cuttings at each end; but with these exceptions the tunnel was mined by a top-heading, 6¼ ft. by 4¼ ft., first being made for the full distance of each length. The crown was protected by larch bars and poling boards, and after the ground was secured, it was gradually widened out to the shape of the tunnel, the same description of timbering being continued to about 10 ft. above the formation level. The contract price for the excavation, including the timbering, was 4s. 6d. per cubic yard. In the construction of a tunnel, the masons, or bricklayers, should, as a rule, commence the lining as soon as possible after the ground was prepared for them by the miners. The lengths mined at each face varied according to the nature of the ground; averaging, in loose shale, 3 lineal yards, through stony shale 5 yards, and through rock 8 yards, or in some instances 10 yards. The prices paid to the miners ranged from £8 to £18 per lineal yard, one half of the total length amounting to £12, or less.

The centres used were skeleton ribs, set about 1¼ yard apart; but at the leading ends two ribs were fixed close together. This description of centering was found to answer very well. The price allowed for setting each rib was but 8 shillings. The masonry of the side walls was of coursed rubble. The arch for a length of 632 lineal yards was turned with fitted rubble; but owing to the scarcity of good bedded stone, the remaining length was built of brickwork. The average quantity of masonry per lineal yard was 12½ cubic yards, and the contract price throughout, 20s. per cubic yard. The mortar was composed of Barrow stone-lime mixed with coal-ashes, in the proportion of 2 to 1, ground by heavy iron rollers, and used fresh. Its setting properties were most satisfactory. The spaces between the crown bars, called the mid-feather, were filled up with brickwork, and the bars themselves were left in where they had "sagged."

The first length of the tunnel was keyed in on the 27th of October, 1854, and the last was finished on the 21st of March, 1856, a period of seventeen months, or equivalent to about 80 lineal yards completed per month, exclusive of the sinking of the shafts. The contract price for the tunnel was £26 per lineal yard through rock, and £35 16s. per lineal yard through shale, the average price being about £30 per lineal yard.

The Buckhorn Weston Tunnel, on the Salisbury and Yeovil Railway, was 739 lineal yards in length, 25 feet in extreme width, and 20 feet in height above the level of the rails. It was constructed through Kimmeridge clay, intersected with veins of loose rock. These veins acted as conduits for a large body of water, amounting to about 90 gallons per minute, which flowed in at the crown of the tunnel for nearly one-half its length. To remedy the evil effects arising from this volume of water, a heading 5 ft. by 5 ft., was driven above the tunnel, and about 10 yards on the upper side of it, for a length of 200 yards. A pipe, 12 in. diameter, was laid in this heading, and the remainder of the space was filled in with loose stone. The water was thus intercepted, and conveyed away from the work. It was originally intended to execute this tunnel by means of a bottom heading, sufficiently large for ordinary waggons, from the cutting at the west end, and to sink two shafts.

After the heading had been driven for a length of 200 lineal yards, it was found that the action of the atmosphere caused the sides to bulge in so much that this plan had to be abandoned. A smaller heading was then substituted, and three additional shafts had in consequence to be sunk. The shafts, which were only temporary, were 8 ft. square, and were lined with timber. Their cost amounted to £1 10s. per lineal yard of tunnel.

The mining was performed in a similar way to that of the Lydgate Tunnel; a top heading being first driven from each shaft. The average price for mining and tipping was 4s. 6d. per cubic yard, and the quantity amounted to 80 cubic yards per lineal yard of tunnel. The lengths mined at each face ranged from 3½ lineal yards in heavy ground, to 5 lineal yards in favourable strata. The average cost of mining was £30 per lineal yard, exclusive of the shafts. The crown bars were of larch, 18 in. diameter, and were fixed about 18 in. apart.

The centres were strongly braced, and were placed about 1¼ yards apart. Each rib contained 35 cubic feet of timber, and 285 lb. of wrought iron in bolts and straps, and the cost of setting amounted to 6s. per lineal yard of the tunnel. As side pressure was anticipated at the commencement of the work, the first ten lengths were built with an invert, which contained 4 cubic yards of brickwork per lineal yard. Further experience showed, however, that this was not necessary. The tunnel was built throughout of brickwork, upwards of six millions of bricks being used, and the average quantity per lineal yard of tunnel was 20 cubic yards. For a length of 390 lineal yards, where the water occurred, the work was 2 ft. 8 in. in thickness. The spaces behind the brickwork were filled in solid, and throughout the heavy ground three bars were left in, on an average, in each length. As there was no sharp sand in the neighbourhood, burnt clay, fine sand, and broken bricks were ground together, and mixed with Bridgewater hydraulic lime in the proportion of 2 to 1; the result was perfectly satisfactory.

The first length of this tunnel was keyed in on the 6th of October, 1858, and the last was completed on the 17th of February, 1860, a period of sixteen months. The total cost had amounted to £53,000, or £72 per lineal yard; detailed particulars being given of the cost of the different items.

ACTION OF HEAT AND FORCE UPON MATTER.

A PAPER on this subject was read before the Manchester Literary and Philosophical Society, by Mr. J. C. Dyer.

Confining his observations to the "action of mechanical forces"—apart from those depending on the electrical magnetical, and vital forces —he held the former to depend on the inherent properties of matter, as gravity, inertia, and elasticity, each coextensive with the material universe.

That force cannot in any case be treated as an abstraction or as apart from the matter in which it resides, though several authors have had recourse to such an abstraction to account for phenomena attending the operation of force. Mechanical action, depending on the elastic force generated by the agency of carbon and water, being of so great importance, it is desirable to obtain some settled knowledge as to how this arises. We all know that by combustion of the former the latter is converted into steam. That which passes from the burning coals through the boiler plates and into the water to form the elastic vapour, is called heat; but whether it be a union of heat with the water, or only a transmitted mechanical action on the water, causing its atoms to separate and assume the elastic state, remains a question for solution; and of late several able writers have offered explanations of this phenomenon founded on the supposed nonentity of heat and the agency of mechanical force to form steam, and thus rejecting the latent heat theory which before seemed to account for the heat absorbed to form steam. So far as the latent heat theory serves to explain phenomena, the mechanical creation of heat is uncalled for, since it is unphilosophical to assign new causes when those before accepted clearly met the case. Yet we have seen two elaborate essays, by Mr. W. J. M. Rankine and Professor Tyndall, each based on the force heat assumption, but without affording any solid proofs of its application to the phenomena adduced by them.

Mr. Rankine states that "heat produces an increase of temperature and of expansive force in bodies; that the changes from the solid and liquid states to the gaseous state, is accompanied by an increase in volume; that heat which produces those effects is known by the name of sensible heat, as attaining the form of heat, and in short making the body hotter." Again, that "changes of volume are attended with changes of molecular arrangement, perceptible or imperceptible, and that the latent heat of expansion or evaporation consists of heat that disappears in overcoming pressure and the attraction of the particles of the body." In reference to the nonproduction of heat by the moving force exerted in waterfalls, the following solution is offered, viz.: "It is natural to suppose that the motion during this phenomenon (the falling of a mass of water) has not been destroyed, but has been converted into revolutions of the particles in vortices or eddies too small to be perceptible by any of our means of observation, and that the centrifugal force of such eddies is the cause of the tendency of hot bodies to expand, melt, and evaporate."

The first-class of phenomena above cited are plainly accounted for by the doctrine of latent heat, but the latter explanation about waterfalls passes Mr. Dyer's comprehension. He submits that what is said to be natural to suppose concerning the revolutions of particles in vortices and eddies too small to be perceived is too obscure and questionable to be accepted in explanation of anything. If Mr. Rankine has no better mode of accounting for the nonappearance of heat from the force expended in waterfalls than the above, his defence of the generation of heat by force fails, and the balancing the force by the resistance at the foot of the falls is just as open to view as the falling force itself; so that the motions, too small to be perceived, are supererogatory inventions. The dynamical origin of heat is also set forth by Professor Tyndall, in a Paper "On the Forms and Action of Water." Examples are therein adduced of vast mechanical forces exerted by the formation of water, and by its changes from the states of a solid, liquid, and vapour. He says that "on the combination of oxygen and hydrogen to form water weighing 10lb. an energy was expended, the atoms clashing together with a force equal to that of a ton weight let fall from a height of 23,757 feet. In falling from the state of vapour to that of water an energy was expended equal to that of a ton falling from a height of 3,700 feet, the moving force of the stone avalanches of the Alps was but as that of snow-flakes, compared with the energy involved in the formation of a cloud. In passing finally from the liquid to the solid state, the atoms of 10lb. of water exercised an energy equal to that of a ton weight falling down a precipice 550 feet high."

Now, the union of the gases to form water, the evaporation of it to form steam, and freezing it into ice, are chemical changes, and the forces called into action by them are chemical forces, which cannot be measured by that of gravity in falling tons or even ounces; but the mutations of heat attending those changes are measured by degrees, when passing from the latent to the sensible state, and *vice versa*. Of vapour in the air, the Professor says, that "though forming only about 0·5 per cent. of the atmosphere, for every ray of terrestrial heat struck down by the air, fifty, sixty, or seventy rays were destroyed by the aqueous vapour. This vapour permitted the solar rays to reach the earth, but intercepted the terrestrial rays in their escape towards space," and he adds that "in the presence of such experiments, it was easy to see how the snow of the Alpine mountains, and how the ice, should be squeezed through the moulds formed by the valleys, and then these mountain glaciers were as much a proof of heat as of cold, and to produce the vapour to condense and form glaciers required as much heat as would raise five times the weight of the glaciers of cast iron to its melting point." The heat required to convert water into steam as it passes from the sensible into the latent state is a known quantity, so also is the amount required to convert ice into water; but that required to melt a pound of ice and evaporate a pound of water would fall far short of melting five pounds of cast iron.

That no mechanical energy is exerted in the conversion of water into steam is obvious to our senses, since evaporation is the most gentle, imperceptible, as well as the most universal action in Nature's laboratory; and although the elasticity of the steam itself exerts mechanical force equal to the atmospheric pressure, chemical force alone is concerned in evaporation, and therefore cannot be compared with falling bodies, so that the alleged energy and clashing force of atoms, in the actions of water cited, are wholly imaginary; nor can philosophy assert any fact relating to mechanical action which cannot be proved by experiment or established by plain induction; and in the cases cited, no one can know anything about the occult forces and energies of the motions of atoms attending the mutations of water. Great respect is due to both of the gentlemen whose essays have invited the above strictures; but the search after the truths of science "should not halt before high names."

Mr. Rankine, in offering demonstrations of the dynamical origin of heat, allows that heat disappears and becomes latent in water, in passing from the solid to the liquid state, and from this into vapour, as also that the same amount of heat is given out and reappears as sensible heat, upon the reversal of those changes; thus in substance admitting the latent heat doctrine, whilst denying the materiality of that which does so enter into a latent and reappear in a sensible state, and calling this heat the production of force, when no mechanical force whatever is called into action by those mutations of water. They are, however, plainly explained by the agency of heat, in its chemical union with water and its evolution from water. Although the evolution and absorption of heat from the compression and expansion of elastic fluids bears a constant relation to the amount of compression and to the compressing force, yet this is not the case, as Mr. Rankine supposes, in the resistance to compressing forces by liquids and solids; the amount of compression in these latter cases depends upon the relative mobility of the particles of the bodies, and we find forces of great energy, exerted against yielding solids, as in carriage and other springs and elastic bodies, are in continuous action without producing any sensible heat when no compression takes place. If it were true that acting forces always produced their equivalent in heat, then the powerful movements of railway springs, hydraulic presses, and the like, should raise intense heat in the steel springs and water exerting such force, and the absence of any heat in such cases must be fatal to the dynamic creation of heat.

EXPERIMENTS IN EXPLODING FIELD MINES BY ELECTRICITY.

THE editor of the Washington *Chronicle* gives the following description of some experiments which he recently witnessed with field mines, which were exploded near the forts on the Virginia side of the Potomac by means of electricity :—

Arriving on the ground, we learned that His Excellency the President was there, accompanied by the Secretary of War, General Heintzelman, General Barnard, General Abercrombie, and many other officers of less note. Soon after there was a gaeat explosion immediately in our front; the earth opened and vomited forth stones, shot and shell, vertically, horizontally, and, in fact, in all directions.

Immediately around us were a number of the officers of the signal corps, busily engaged in connecting the wires of a field telegraph to its support, and among them we saw Professor Beardslee, the inventor of the telegraph apparatus now used in our armies. From him we learned that he was exhibiting the application of his new electro-magnetic machine to the explosion of mines, and that he was now ready to fire another.

Quick as the wires could carry the spark there was another explosion even greater than the first, and the air was again filled with earth and smoke, stones and exploding shells; some of the latter falling in uncomfortable proximity to our person.

A third mine was exploded in the same manner. In fact, we should judge from appearances that the ground in front of our forts had been extensively mined, and it is only necessary for Professor Beardslee to connect his apparatus with them, pass the word, and they will be exploded.

An order was now passed from Col. Alexander, of the Engineers, who appeared to have charge of the operations, for the crowd to fall back to a greater distance, as a *fougasse* was about to be fired.

Taking up our position close to the President, we watched for the *fougasse*. We heard a heavy explosion, as if some of the internal fires of the globe were escaping, and the earth belched forth a volcano of smoke, stones, and exploding shells, even more fearful than before. It rained stones for acres around and in front of it, and must have carried annihilation to any assaulting column in the neighbourhood. Immediately after this explosion, there was a rush of the soldiers to see the *fougasse*, but a heap of ruins only showed where it had been placed.

CHILDS' MACHINERY FOR CUTTING VENEERS.

FIG. 1.

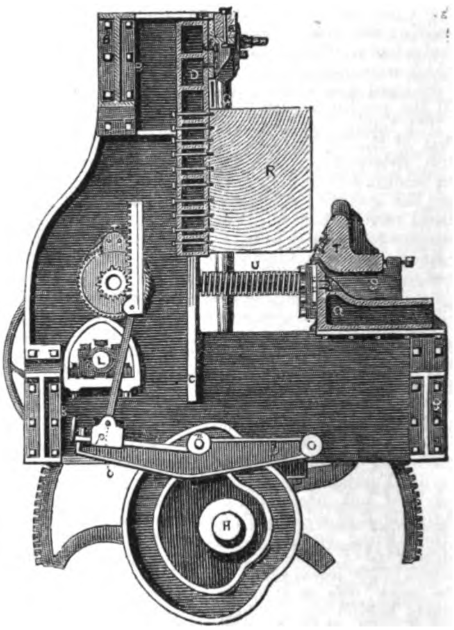

FIG. 3.

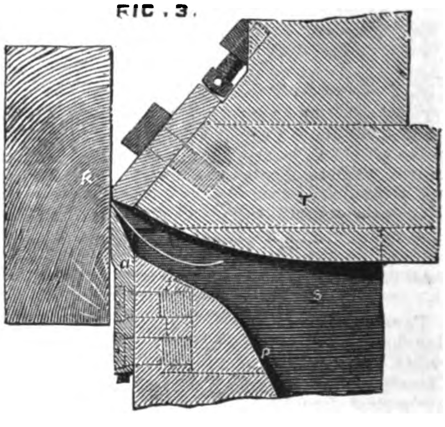

CHILDS' PATENT MACHINERY FOR CUTTING VENEERS.

MR. A. B. CHILDS, of Oxford-street, has recently obtained a patent for improvements in machinery for cutting veneers. The invention is illustrated in the annexed engravings.

For this purpose the log or block from which the veneers are to be cut is firmly secured to a bed plate by means of bolts which pass through the bed plate and screw into the log or block. The bed plate is perforated with holes at equal distances apart, and a sufficient number of them to receive a requisite number of bolts to hold the block firmly thereto. The bed plate may be placed in a vertical, a horizontal, or a diagonal position, but it is preferred to place it in a vertical position. The bed plate, together with the block carried thereby, has a motion up and down a distance somewhat over and above the width of the largest block to be cut; and this motion is by preference communicated to it by means of two cranks and two connecting rods, one at each end of the bed plate. The knife, when making the cut, is stationary, but is capable of being moved towards and from the bed plate by the action of the feed motion, which, by means of a double ratchet, causes it to recede immediately after the cut, and again to move forward immediately before the cut a distance depending on the thickness of the veneer next to be cut. The knife consists of a straight cutting edge with one side bevelled off, and is firmly secured to a knife block which is made to slide towards and from the bed plate. A little before the edge of the knife there is a pressure bar made adjustable by set screws and bolted firmly in its required position to a pressure beam so as to give a very heavy pressure on the surface of the block immediately on the point or line of cut. The pressure beam is also made adjustable by set screws, so that it may be set towards or from the edge of the knife, according to the amount of pressure required and the thickness of the veneer to be cut, and then held firmly to the knife block in its required position by means of bolts. The knife block is held firmly in its relative position to the bed by means of powerful feed screws, so that any amount of pressure required can be given to the pressure bar.

The main feature in this invention is the peculiar method of applying the pressure to the surface of the block, at or near the line of cut and of graduating the same to the different thicknesses of veneers; also the method of feeding the knife and of graduating the feed to the different thicknesses of the veneers to be cut. By this method veneers are cut more perfectly and sound, and more free from cracks, from any kind of wood and to any thickness required.

Fig. 1 is an end elevation; fig. 2 is a vertical transverse section; fig. 3 is a vertical transverse section of the knife and pressure bar on a larger scale.

The frame is composed of two slide pieces A, A, and three girts B, B, B, secured together with bolts. There is a vertical guide C formed on each of the side pieces A, A, projecting inwardly, and a bed plate is fitted to slide freely thereon. A cross head E is bolted to the upper part of the bed plate D with a wrought-iron cross beam F secured thereto; this cross beam is longer than the bed plate or cross head, and extends out by the frame at each end with wrist pins made thereon, to which the upper end of the connecting rods G, G, are attached. The main shaft H is hung below the frame, and fitted to revolve in boxes or hangers, which are bolted to the bottom of the frame; this shaft has a large gear wheel fixed on each end outside of the frame with a crank pin K set therein, to which the lower end of the connecting rods are attached; the crank pins are set a suitable distance from the centre to give the required motion or length of stroke to the bed plate. The driving or pinion shaft L is fitted to revolve in boxes, which are set in the rear part of the frame; this shaft has two pinions fixed thereon, one near each end outside of the frame, that gear into and drive the large gear wheels J. A portion of the lower part of the sides of the frame project out in front a distance sufficient for the knife block Q to rest and slide upon. The knife block extends across from one side of the frame to the other. The knife *a*, shown more clearly in Fig. 3, is secured to the block and made adjustable by a series of set screws. A portion of this knife on the side next to the log or block or from the edge downward is ground straight or in a vertical plane, so that it may have a bearing against the wood a little below the edge of the knife, or, in other words, a continuous bearing from the edge a short distance downward. The knife block at each end has an upward projection S, on which the pressure beam T rests; the pressure beam extends the entire length of the knife block, and has its bearing at each end, and is made adjustable by a set screw, and when properly adjusted it is firmly secured at each end to the knife block by bolts, which screw down into the projections S, S. The pressure bar *d* stands at an angle of about forty degrees from the plane of the bed plate, and in that position is held firmly to the pressure beam by a series of bolts; the pressure bar is also made adjustable by set screws *f*. The peculiar shape of the lower part of the pressure bar directly back of the cutting edge of the knife is an important part of this invention; it is its peculiar shape directly in front of the cut, and the amount and manner of applying the pressure, that enables the patentee to cut veneers without cracking the wood in process of cutting.

It is necessary to have a very heavy pressure directly on the line of cut with a slight compression of the wood below the cut, and gradually diminishing to nothing in order to cut the veneers without cracking them.

The operation of the machinery is as follows:— By giving motion to the large wheels by means of the pinions, the connecting rods and the block of timber R will be made to slide up and down on the guides and cut a veneer from the block at every revolution of the large gear wheels J, J. During a portion of the downward motion of the bed plate while the cut is being performed, the roller *n* rolls on the smallest part of the cam Z, which is on a true circle from its centre, thereby allowing the lever *l* to remain at rest in its lowest position during the whole time the cut is being performed. Immediately after the cut is completed, and while the crank pins are passing under the centre, the cam lever *l* rises to its highest position, forcing the rack *u* upward with it, which causes a pinion in connection with levers and panels to turn to move the knife block a sufficient distance to allow the log or block R to pass up without touching the edge of the knife *a*. During that portion of the upward motion of the bed plate, while the log is passing the knife *a*, the roller *n* rolls on the largest part of the cam Z, and immediately after the log R crosses the knife *a*, the cam lever together with the rack *u* drop to their lowest position again, thereby causing the knife block to be fed forward a distance depending on the thickness of the veneer next to be cut, in addition to the back motion before given. By this arrangement for a feed motion wood can be cut to any thickness required, from the very thinnest veneer up to three-sixteenths of an inch in thickness. The use of the slide block *p* is to vary the distance of motion given to the rack *u*; for instance, if by changing the ratchet one tooth should be found to be too great a change, the side block *p* can be set so as to take any part of a tooth, even the hundredth part, if required, thereby graduating the thickness of veneers to any point of nicety required. This slide block can also be used to change the distance of motion required to be given to the rack *u* from thick veneers to thin, and from thin to thick. When the log or block R is entirely cut up into veneers a thumb screw is turned so as to raise the pawls up, to enable the ratchet to revolve freely in either direction; the knife block may then be run back by attaching a belt to the pulley on the feed shaft *j*, or by any other practical device.

BROWNE AND ARMSTRONG'S GAS METERS.

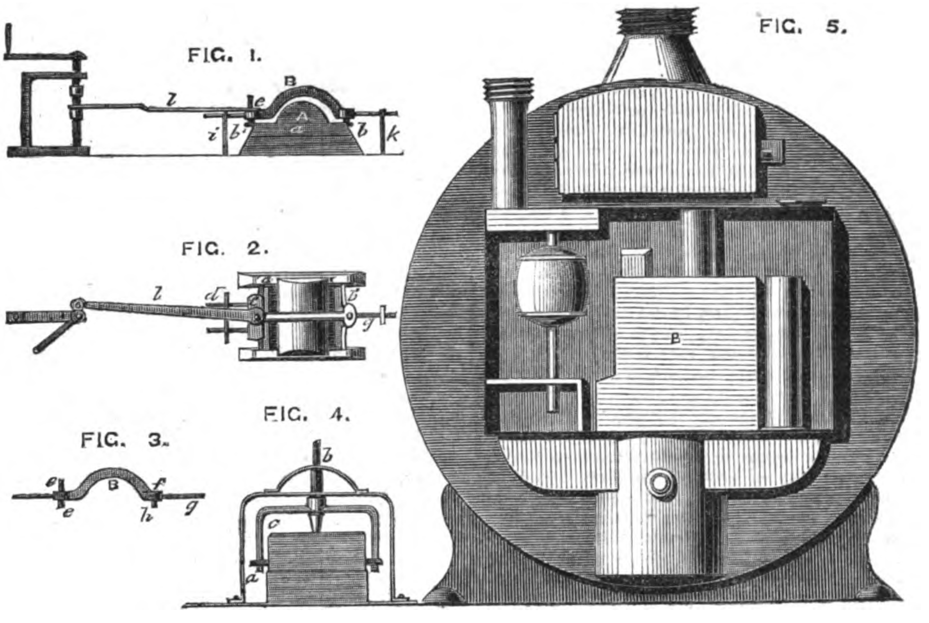

FIG. 1.

FIG. 2.

FIG. 3.

FIG. 4.

FIG. 5.

BROWNE AND ARMSTRONG'S IMPROVEMENTS IN GAS METERS.

In meters as at present constructed much gas passes unmeasured during the too and fro movement of the valves, by the pressure of the gas raising the valve from its seat, both in wet and dry meters; this may be entirely obviated by the use of the valves recently patented by Mr. W. H. Browne, of Theobald's-road, and Mr. H. Armstrong, of Manchester-street, which we illustrate in the annexed engravings.

The invention, as far as relates to dry meters, consists—first, in means of causing the efficient working of the ordinary slide valves. This is accomplished by connecting each slide valve loosely to a frame carried over or round the valve furnished at back with a pin which works in a hole formed in an upright, while the other end of the frame is united to the connecting rod, whereby motion is communicated to the valve; pins also project from the fore part of the frame, and work in holes formed for their reception in other uprights. By means of the frames, the action of the valves both in advancing and in the back stroke is the same, that is to say, the valves are drawn in both directions, in contradistinction to their being drawn in one direction and pushed in the other. Second, in driving rotary valves in dry gas meters from the lower part of such valves. For this purpose eyes are fixed in the lower part of the rim of the valve, and a wire or wires fastened on the valve spindle are passed through such eyes. The main purpose of the improvements before alluded to is to prevent the valves from being lifted from their seats, and thus allowing the gas to pass unmeasured, as occasionally takes place with valves as ordinarily fitted and constructed.

Fig. 1 of the engravings is a side elevation, and fig. 2 a plan. A is the valve, free to move to and fro on the surface framing of the ports. The valve is formed in a piece with side frames *a a*, and *b* b^1 are cross-bars between the ends of the side frames; these cross-bars have a hole or aperture made about the centre to receive studs from a loose frame B, now about to be described. This frame B is shown detached in side elevation at fig. 3; it is bent to fit over the valve A; *c* is a cross-head, in which one end of the frame terminates, into which two horizontal guide-pins *d d* are screwed or otherwise fixed; *e* is a vertical stud, which projects both above and below the cross-head *c*; *f* is a similar but smaller cross-head at the opposite end of the frame, carrying a horizontal guide-pin *g*, and a vertical stud *h*, projecting from the under part of the cross-head *f*; *i* is an upright, carrying two eyes, in which the guide-pins *d d* move to and fro; and *k* is a similar upright, with one eye, in which the guide-pin *g* works; the lower part of the vertical stud *h* enters the aperture formed in the cross-bar *b*, while the vertical stud *e* enters the aperture in the cross-bar b^1; the connecting-rod *l* is connected to the frame B by an eye in one end thereof, through which the upper part of the vertical stud *e* passes; the other end of the connecting-rod is attached to a crank in connection with the index. As many similar valves to that shown in the drawings may be fitted to a dry gas meter as may be required.

Fig. 4 is an external elevation of a rotary valve for dry gas meters; *a a* are the eyes, which are fixed at the sides and on the lower part of the valve; *b* is the valve spindle, and *c c* wires fastened thereon, the lower ends of which we pass through the eyes *a a*.

The improvements in wet gas meters thus consist in forming an enclosure, open at top, round the aperture leading from the float-case into the drum of the meter, and in making the aperture of very small diameter, in order to prevent any sudden pressure acting directly or without check in the float-case, and thereby forcing and keeping down the float.

Fig. 5 is an elevation of a wet gas meter, the float-chamber having the front plate removed. A is the float, B is a three-sided partition fitting against the drum-case and the bottom of the float-chamber, but open at top; a small aperture is made in one of the sides thereof, through which communication for the water in the float-case and inside of the partition and interior of the drum takes place. C is the overflow pipe, which we prefer to place outside of the partition.

W. CLISSOLD'S DRIVING BELT.

We last week alluded at some length to the interesting subject of machinery belts, and we also gave a short account of the belt patented by Mr. W. Clissold, of Dudbridge, Gloucester. The following is a description of this novel mode of constructing that class of driving belts which bind by lateral pressure on their pullies, and thereby take so firm a hold as to remove the liability to slip, which is a disadvantage common to ordinary driving belts. This improved class of belts (which already forms the subject of letters patent granted to Mr. Clissold, and bearing date the 22nd day of May, 1860, No. 1,266,) may be described as an endless band bevelled at its edges to fit into V-grooves formed in the periphery of the driving pullies, such band being composed of layers of leather or other material connected together by pins, or otherwise. In practice it has been found that the beneficial thickness of which these belts may be made is limited, by reason of the unequal strain upon the outer and inner layers, or parts of the material composing the belt, and, consequently, that the strength of such belts cannot with advantage be indefinitely increased. From this cause it was deemed necessary to limit the application of belts constructed of a wedge or taper form in cross section to uses where no great strain was likely to be experienced.

FIG. 1.

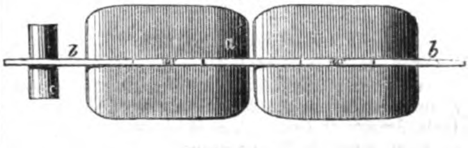

FIG. 2.

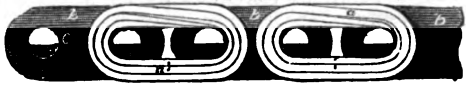

FIG. 3.

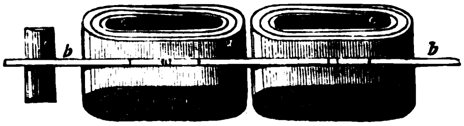

FIG. 4.

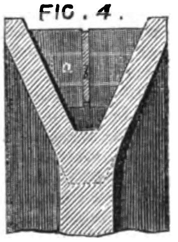


The object of the present invention is to increase the strength of belts of this class so as to render them equal to the heaviest work to which it has hitherto been or may hereafter be found desirable to apply driving belts or bands. To this end, instead of making bevelled edged belts, as heretofore, with one continuous length of bevelled edge, they are formed of links, which, while presenting good contact surfaces to the V-grooves of the pulleys (against which they will press laterally without touching the bottom of the grooves), will so divide the unequal strain upon the inner and outer surfaces of the belt hitherto found so destructive to the wedge form of belt as to render the strain nugatory. The friction or wedge-shaped links may be made of strips of leather or other flexible material coiled up to the ordinary figure of a link, or they may be made of moulded rubber or other suitable plastic material. These links are connected together by link plates carrying a stud at either end, which studs will enter the space in two adjacent flexible links and hold them together, forming, in fact, fulcrum pins for these links to turn on as they pass around the driving pulleys. The accompanying engravings show the improved construction of link driving belt in several views, the friction links being in this example composed of coils of leather. Fig. 1 represents the outer face, and Fig. 2 a side elevation, of a portion of the belt drawn to full size; Fig. 3 is a view of the inner face of the belt, and Fig. 4 is a cross section showing the application of the belt to a V-grooved pulley.

The wedge-shaped links *a*, *a*, fit into the groove of the pulley, but not so as to bed therein, the object being to allow of the belt tightening on the pulley by sinking deeper into the groove as the breadth of the links decreases by wear. These links *a* are each made by preference of two parts to facilitate the forming of sockets for the reception of the link plates *b*, *b*, and the parts *a*, *a*, are coupled together in the middle by filling pieces a^* cemented thereto, or otherwise attached to the parts *a*.

From the above explanation it will be understood that this mode of making driving belts permits of any strength of link being used according to the work to which the belt is to be applied. The patentee also remarks that belts constructed on this principle may be made wholly of metal, in which case he prefers to line the V-grooves of the pulleys with wood, to prevent the grinding of metal against metal.

SEA-GOING SHIPS.

On Wednesday Captain Cowper P. Coles, R.N., delivered a lecture on the subject of "Sea-going Shield Ships," at the lecture-room of the Royal United Service Institution, Whitehall-yard. Sir J. Pakington, M.P., presided on the occasion, over a numerous and evidently an influential audience.

Captain Coles commenced by remarking that at this moment, when the construction of the navy occupied so much general attention, he trusted that no apology was necessary for his entering on the subject. In 1860 he delivered a lecture in that room in which his views with regard to the construction of iron-clad ships of war were first brought before the public. Since that period the construction of line-of-battle ships and wooden men of war might be said to have been given up by all the maritime nations of the world; and the necessity of having armour-plated ships had been so fully recognized that everywhere they were to be found building or built in sizes varying from 7,000 to 700 tons. But the form and construction of these ships were still an open question. It had been said that shield ships could never be good sea-going vessels on account of the great difficulty of masting them; but he was able to state that they could be masted with the greatest ease, and so as to spread one-half more canvas than could be carried in the old method. It must therefore be assumed that they would have a corresponding advantage in sailing. Rigid iron tubes would be used for the lower rigging, and these would form with the mast, also of iron, a tripod. The lecturer pointed to a model representing a shield ship of nearly the same tonnage as the "Defence," and to a diagram representing the ship cleared for action, showing that nothing was left aloft but the iron tripod lower mast. He also showed by the model how the square sail was to be taken in from below, and the yards braced fore and aft. If there should be a breeze the topsail could be kept set so as to steady the ship. The lecturer proceeded to enumerate what he deemed the advantages of the iron tripod mast, which were fully described a short time since in the MECHANICS' MAGAZINE. As to the comparative merits of the revolving shield ships and the broadside ports iron-clad ships now building, he would consider them under the following heads:—Their offensive or destructive powers; their defensive or resisting powers; their speed and sea-going qualities; their light draught of water and handiness in steering. The present transition of navies and the great progress made in constructing large guns, especially in America, left us as little doubt that we were to pass from 68-pounders to 300-pounders as that we had passed from 36-pounders to 68-pounders, and it was clear that the iron-clad broadside ships could not carry this heavy ordnance. The comparative destructive powers of these ships must depend on the weight of the broadside guns as one element of comparison; but it must not be forgotten that a heavy projectile able to destroy a ship might inflict only a small amount of injury if broken up into a broadside. Comparing the "Prince Albert" shield ship with the "Defence" broadside ship as to offensive and destructive power, the broadside of the "Defence" was 560 lb. for a tonnage of 3,700, while the "Prince Albert" threw a broadside of 1,120 lb. for a tonnage of 2,529, with a power of fighting half her guns on either side, giving her, in fact, two broadsides of 560 lb., or making her equal to two "Defences," although the "Prince Albert" was 1,600 tons smaller. This being the case, he was at a loss to know how Lord Clarence Paget came to the conclusion that a shield ship engaged on both sides would be at a disadvantage as compared with a broadside ship, for it was obvious that the "Prince Albert" would be equal to two "Defences" when fighting on both sides. He might go farther, and say that the "Defence" could fight only every other gun, and therefore her broadside was reduced to 280 lb. Besides this, the "Prince Albert" drew 5 ft. 8 in. less water than the "Defence." Captain Coles then went into similar statistics with regard to the "Valiant," the "Warrior," the "Favourite," and the "Royal Sovereign," with a view of proving that under all these four heads there was a great superiority in the shield ships over broadsides, while their light draught of water would enable them to use the present dockyards, notwithstanding their much heavier ordnance. Captain Coles proceeded to explain in detail a model ship, embodying all his inventions, contrasting it in every essential quality with the best specimen of a broadside ship, the "Favourite," the result of which comparison was to show the superiority of his pet invention, the "Naughty Child," over the "Favourite" in every respect. Perhaps not the least important of all the points of superiority of the new invention was that, while in the ordinary broadside vessels the arc of training guns was not more than 40 degrees, in the shield vessel it was as much as 310 degrees. Another was that in the new invention the living and the fighting portions of the vessel were distinct—a consequence of which was that the ship never required "clearing for action," but was always ready. As to the mode of building ships, if his opinion were asked, he would say "protect the vital parts with thick iron plating," but he would reduce the plating elsewhere. Lord Clarence Paget, in the last session, said that he (Captain Coles) was not a shipbuilder, and that his plans were not fit for the public service. How was it, then, that the Government had adopted many portions of his inventions? He did not profess to be a shipbuilder. He was a practical seaman and a gunner, and he had, with the assistance of naval architects, produced plans to meet necessities as they had arisen. Having urged that the adoption of his scheme would save the country millions of money, he thanked his brother officers for their sympathy and assistance, and especially one gentleman whom he saw present, who, when he was struggling on the miserable pittance of a naval captain, came forward and gave him that substantial aid without which his inventions could never have been brought to any practical result."

TRIAL OF THE "ROYAL OAK."

THE official trial of the "Royal Oak" was resumed on Tuesday last. The vessel was steamed some distance below the Nore, and six runs were made at the measured mile at full speed, the following being the results:—In the first run the time was 5min. 30sec., the speed in knots was 10·909, the number of revolutions of engines 60, and the pressure of steam 21; in the second run the time was 4min. 13sec., the speed in knots 14·229, the number of revolutions of engines 59, and the pressure of steam 19½; in the third run the time was 5min. 30sec., the speed in knots, 10·909, the number of revolutions of engines 60, and the pressure of steam 20; in the fourth run the time was 4min. 18sec., the speed in knots 13·953, the number of revolutions of engines 59½, and the pressure of steam 20; in the fifth run the time was 5min. 30sec., the speed in knots 10.909, the number of revolutions of engines 59, and the pressure of steam 19; in the sixth run the time was 4min. 17sec., the speed in knots 14·009, the number of revolutions of engines 61, and the pressure of steam 20. In all the runs the vacuum forward and aft was 24. The mean speed of the six runs was 12·487 knots.

The result of the trial of the "Royal Oak" at full speed may thus be considered satisfactory, when her immense weight and size are taken into account. The engines of the "Royal Oak" are of 800-horse power (nominally), while those of the "Black Prince" are 1,250-horse power; and yet on the occasion of the last trial trip of the latter vessel, she only attained a mean speed of 12·209 knots, the "Royal Oak" thus beating her by a quarter of a knot an hour. The actual displacement of the "Royal Oak" during her trial on Tuesday was 6,500 tons, and this mass was driven through the water at a speed greater than that attained by the largest of the iron frigates, with the exception of the "Warrior." Thus far, says the *Times*, then, the Admiralty may congratulate itself on the perfect success which has been obtained by the first of the squadron of iron-clads so far as its steaming qualities are concerned. At the termination of the runs at full speed, it was determined to try the vessel at half-boiler power, and four runs were accordingly made at the measured mile, with the following results:—In the first run the time was 6min. 45sec.; the speed in knots, 8·889; the number of revolutions of screw, 47; and the pressure of steam, 19; pitch of screw, 27ft. 6in. In the second run the time was 5min. 9sec.; the speed in knots, 11·650; the number of revolutions of screw, 49; and the pressure of steam, 20; pitch of screw, 27ft. 6in. In the third run the time was 6min. 29sec.; the speed in knots, 9·254; the number of revolutions of screw, 47; and the pressure of steam, 20; pitch of screw, 27ft. 6in. In the fourth run the time was 5min. 46sec; the speed in knots, 10·405; the number of revolutions of screw, 47; and the pressure of steam, 20; pitch of screw, 27ft. 6in. In all the runs the vacuum fore and aft was 24. The average speed of the four runs at half-boiler power was 10·140 knots. At the termination of the trials of speed some experiments were made in order to test the time in which the half-circle would be made. Four runs were accordingly made with the following results:—First run, helm put hard a-starboard, with four men at the wheel, and the rudder at an angle of 18 deg., half circle made in 2min. 29sec.; second run, helm at port, and rudder at 17 deg., half circle made in 2min. 34sec.; third run, helm at starboard, half circle made in 2min. 42 sec.; fourth run, helm at port, circle made in 2min. 39sec. At half-boiler power the helm was put hard a-starboard by four men with three turns of the wheel, and the rudder at an angle of 15½ deg., when the half circle was made in 3min. 40sec., the screw making 39 revolutions per minute, and the diameter of the circle 300 yards. The helm was then put hard a-port, at an angle of 14½ deg., and the half circle made in 3 min. 32sec. Commander Crewe-Read, who superintended the trials, then directed the helm to be put hard a-starboard to an angle of 18 deg., and the ship going at full speed, with the screw making 54 revolutions, the complete circle was made in

6min. 38sec., the diameter of the circle being a little more than double the vessel's length. During the trials, which were protracted until a late hour on Tuesday afternoon, the "Royal Oak" was found to answer her helm remarkably well, and was steered as easily and expeditiously as a river steamer.

The boilers generated a full supply of steam, and the engines worked with remarkable steadiness and precision, and with scarcely the slightest vibration. The average temperature of the stokeholes, with 24 furnaces at work, during the trials, was 78 deg., and the engine-room 62 deg.; this low temperature being attained by the admirable ventilating apparatus fitted on board the "Royal Oak," by the inventor, Mr. Baker, Chief Engineer of Chatham Dockyard. As a comparison, it may be mentioned that the average temperature of the upper deck was 58 deg., and that of the lower deck 64 deg.

IMPROVED BEARINGS OR STEPS.

MR. N. J. AMIES, of Manchester, has lately patented an invention designed for the purpose of dispensing with brass and other expensive metals employed in the manufacture of "steps" or "bearings," and it consists in the substitution and use of malleable cast iron for the exterior or case, and in filling the interior or parts subject to friction with any well-known non-metallic antifrictional composition, or with one consisting of caoutchouc, gutta percha, or other elastic gums incorporated with plumbago, steatite, or plastic, earthy, or metallic matters bound together atomically with vegetable or animal gums or size, and in such proportions as, when dry, to form a hard and solid filling for the aforesaid hollow case. This composition constitutes the second part of the invention, and may also be used for bearings by itself, the chief feature being the combination of the aforesaid ingredients or others equivalents to the entire exclusion of all vegetable or animal fibre, such composition exciting less friction, and consequently is better adapted for steps or bearings than when fibrous materials are combined therewith.

The bearings, journals, or steps are to be cast of malleable cast iron, and formed with cavities or recesses, for the filling of the aforesaid composition is to be opposed to the frictional surface requiring lubrication, and which may be made of caoutchouc, gutta percha, or other elastic gum, one part; plumbago, steatite, or plastic, earthy, or metallic matter, three parts; and vegetable or animal gum or size, one part; or such other component parts as may be found desirable; but when water or liquid in a heated state has to come into contact with the composition, the inventor prefers to employ a gum called "rhus copallinus" (gum copal) which is better calculated to resist the action of heated liquids. He also states that this composition may be employed alone, suitably cast or formed without the addition of wood or metal.

OXALIC ACID FROM SAWDUST.

AT a recent meeting of the Pharmaceutical Society of Great Britain, held in George-street Hall, Edinburgh, Dr. Murray Thomson, F.R.S.E., read a paper on Mr. Dale's new patent process for the manufacture of oxalic acid from sawdust, acted upon by alkali, lime, &c. Dr. Thomson illustrated his remarks by specimens and drawings, all of which were viewed with much interest by the meeting. It appeared from the statement in the paper that, by proper manipulation, 2 lb. of sawdust wére made to yield 1 lb. of oxalic acid; and that during one part of the process most of the alkali employed was recovered, and used again in succeeding manufactures. The produce in Mr. Dale's establishment was weekly about nine tons' weight—an amount more than half of the oxalic acid believed to be used all over the world. A vote of thanks was cordially awarded to Dr. Thomson for his communication.—Mr. John Mackay described and submitted various specimens of the new French carboniferous preparations about to be introduced to this country by Professors Pichot and Malapert, of Poitiers, for the purpose of disinfecting and dressing wounds, ulcers, &c. After several years' experience in France, the commission for inquiring into new medicines and remedies instituted by the General Administration for Public Assistance, as well as by the Military Council of Health at Paris, have decided that the preparations be approved of, and placed at the disposal of the surgeons of public institutions, both civil and military. The different forms are charpie, sachets, paper, and tissue. An agent having been appointed in London, there was now every facility for procuring the various forms, and they would therefore doubtless be soon practically tested by the medical authorities here.—Notices were given regarding the Prize Essay Committee and the library, after which the meeting terminated.

NEW MATERIALS FOR PAPER.

THE *Wellington Independent*, a New Zealand paper, writes:—"Complaints have been made in England of the want of material for making paper. Straw has been used for the purpose; but surely a much better paper could be made from our common flax and the leaves of the cabbage-tree (and quite as good, I should think, as that made of the old rags which have hitherto been used)? Flax can be had, as we all know, in any quantity; the cabbage-tree is not so abundant; but there need be no lack of this, for, when a tree is cut down to get at the leaves, if the stem is laid in a shallow trench, and slightly earthed up, a dozen young plants will speedily spring from it, and the leaves may be cut in the following year. That these plants (the flax and cabbage-tree) will afford good materials for making paper, I think there can be no doubt; but the question arises, what would be the best form in which to send then to England? This I cannot answer; but I think the subject well worth attention. Would not paper-mills in this country pay well?"

In a late Sydney newspaper, says the *Paper Trade Review*, mention is made of a peculiar vegetable substance, taken from the root of the *Zamia spiralis*, vulgarly known as the native palm. This plant, which flourishes luxuriantly over millions of acres of land in New South Wales and other Australian colonies, otherwise unproductive, seems to possess many properties which would render it highly valuable as a plant of commerce. The substance is a sort of cotton, very short in the staple, but fine and soft, and it would appear to be admirably adapted to the manufacture of paper. Experienced persons state that it would be preferable for this purpose to the refuse cotton of the manufactories of Lancashire, which is bought by the paper-makers at the rate of 6d. a pound. The specimen was collected at the Clyde River, near Bateman's Bay, and is described as forming a kind of external clothing to the fibrous roots of the plant.

The plant also produces a fine gum (resin ?) as pure as amber, which would, doubtless, be available for many purposes of commerce, although the gums exuding from the palm trees of New South Wales have hitherto been found too brittle for ordinary use. The seed of the plant is commonly used by the aboriginal natives as food, and may be readily manufactured into the finest starch and farina, the latter property of the plant having been well known and acted on by settlers in the district for some time past.

ON A NEW FORM OF SPECTROSCOPE.

BY DR. WOLCOTT GIBBS.

MESSRS. J. and W. GRUNOW, the well-known opticians of New York, have just completed, at my suggestion, a spectroscope involving a new principle, or rather one for the first time applied to instruments of this kind. In this instrument the prism of flint glass has a refracting angle of only 37 deg.; the rays which diverge from the slit are rendered parallel in the usual manner, by an achromatic lens having the slit in its principal focus. The bundle of rays then falls upon the first surface of the prism at a perpendicular incidence, and of course makes an angle of 37 deg. with the second surface. Under these circumstances, the refraction takes place at an angle so near the limiting angle that the refracted rays emerge nearly parallel to the second surface of the prism. The amount of dispersion produced in this manner is very great, while the loss of light, occasioned by reflexion at the first surface in the prisms of 60 deg. placed in the position of least deviation, is avoided. The spectrum thus produced possesses remarkable intensity, and the dark lines are seen in countless numbers and with great distinctness. The instrument in this form is sufficient for all chemical purposes; but it is so constructed as to permit the use of a second prism, by which the length of the spectrum is of course greatly increased. Though the telescopes are only six inches in length, with a magnifying power of about 6, the spectrum compares very advantageously with that of a large apparatus with telescopes of eighteen inches focal length and one and a half inch aperture, and a prism of 60 deg. I may mention that the centre of the second surface of the prism lies in the vertical axis of the instrument, and also that in a prism of this kind the refracted rays diverge as if from a single radiant point (which is not the case with prisms of the ordinary construction), the angular dispersion being at the same time much greater. So far as I have been able to find, this form of prism was first employed by Matthiessen. In a lithographed copy of Regnault's "Lectures on Optics" at the College de France in 1848, prisms on this principle, of various forms, are figured and described, together with the spectra produced. These last exhibit an extraordinary extension of the violet end of the spectrum. A Matthiessen prism of flint glass, in which the first surface is concave so as to admit the addition of a double convex lens of crown glass, appears to be preferable for the spectroscope, in consequence of the saving of light.—*Silliman's "American Journal,"* January, 1863.

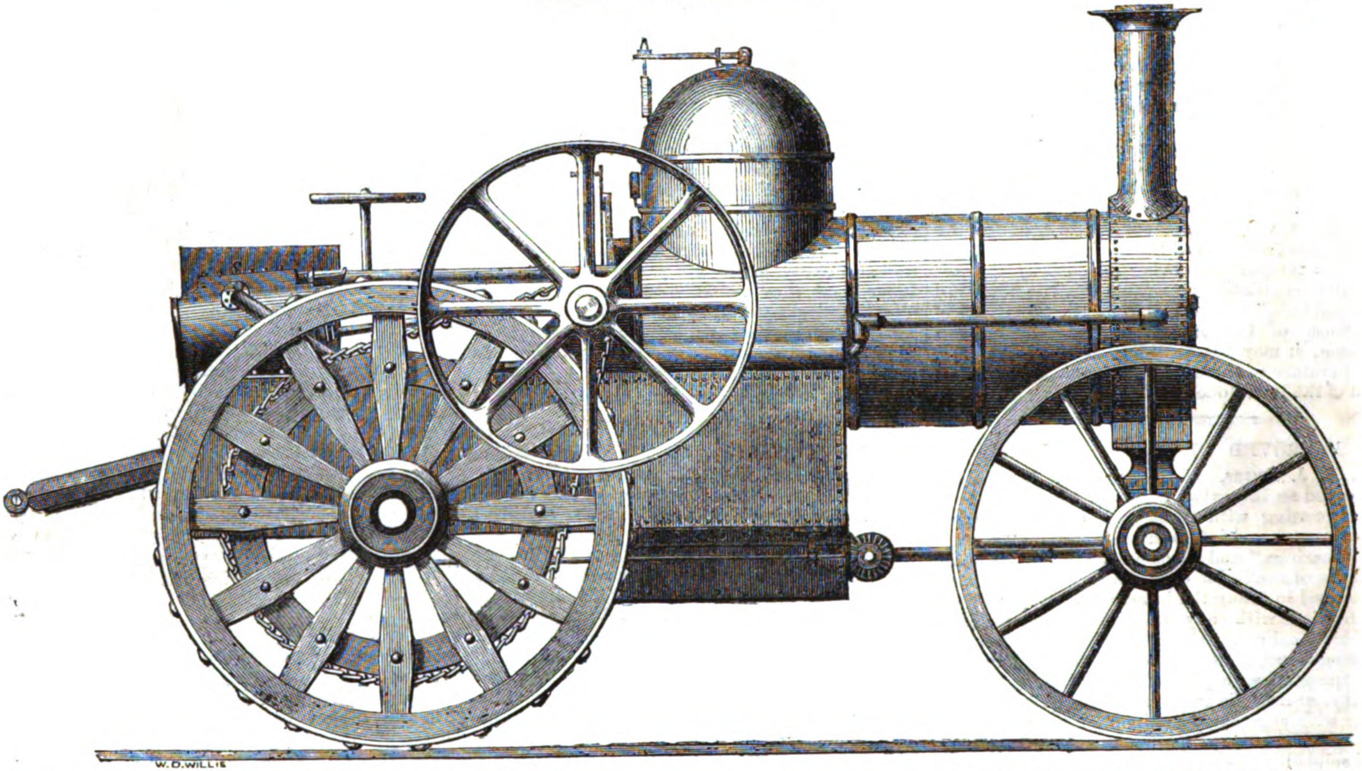
TREUILLE AND TRAXLER'S PAPER FOR DOCUMENTS.

THE experience of the paper manufacturer, says the *Paper Trade Review*, is always finding new modes and elaborating old methods for the improvement of his handicraft. There is constantly some new process discovered which puts the old into disuse, and makes the stability of our occupations impossible. The improvement to which we have now to call attention is, perhaps after all, more fanciful than of much practical utility, either to the manufacturer or to the public. Admitting even that it does not add greatly to the service of the public, we cannot but award it the highest praise for its ingenuity and skill. It is lamentably well known that our public documents of value and importance are often tampered with by the dishonest and fraudulent. This improvement is intended to reduce their chance of success to the smallest minimum. The paper made by this new process consists of a sheet made up of several layers of pulp laid over each other, of different qualities and colours, as may be required.

To hinder the falsification of documents, it is merely necessary to colour the pulp which forms the middle layer, with a colour which would be acted upon by the chemicals employed in cancelling the writing. The document would be thus injured, and it could not be again restored in colour while the surface remains white.

We will now proceed to detail the process of manufacture:—Three vats are employed. The first vat, which contains a weak solution of white pulp; the next vat contains hemp, or common-coloured pulp, requiring a stronger pulp than the first; the third vat contains a greater amount of white pulp. A layer of white pulp is first taken in with the mould; it is then dipped into the second vat to receive a second layer of coloured hemp; thereafter the third layer of white pulp is added. In order to prevent the first layers from breaking in the subsequent pro-

GILES'S TRACTION ENGINE.



cess, the mould should be lined with a piece of wire-work. The intermixing of the coloured pulp with the white is prevented by placing the mould, which has received the first layer, in a casing with a wire-work bottom, so as to prevent the parts which are not covered by the first layers from being brought in contact with the pulp in the next vat—the casing being intended to take in the pulp whereby to forward the coloured layer.

GILES' TRACTION ENGINE.

There is no doubt that one of the greatest impediments encountered in the use of the traction engine on common roads, consists in the difficulty of getting a sufficient grip on the ground. The following is a description of a traction engine, patented by Mr. Giles, of 69, Basinghall-street, and of the means he adopts in order to overcome the difficulty we have alluded to. The engine is four-wheeled, and is carried on springs; it has double cylinders, 6 in. diameter and 10 in. stroke. The traction engine is poetically called a "steam bull" by Mr. Giles. The improvements he claims consist in the embodiment of the principles of "animal tractive efficiency" in a locomotive engine, the motive power of which may be steam or any other suitable agency. Locomotive engines hitherto constructed by Mr. Giles for the purpose of applying these principles to locomotive traction, have had their power made available through the agency of two or more levers (jointed or otherwise), which, representing the legs of an animal, and furnished with extremities representing feet, operate alternately on the ground over which the engine travels, imitating the pedal motions of an animal. Now these improvements consist in a method by which the principles of pedal traction are rendered effective in a wheeled engine without the aid of the aforesaid propellors or levers. The chief feature consists in the embodiment of the principle of animal traction in conjunction with a constant rotary motion, and by which the periphery of one or more wheels is made to manifest, at its point of contact with the surface on which it travels, a tractive adhesion equal to and based upon the same principle as that of the foot of the quadruped when employed as a tractive agent. The following is the mode of obtaining the above result:—At each side of the engine or boiler is fixed a stud, pivot, or other similar apparatus upon which works a lever or flat bar. The stud is fixed at a point on the engine forward of the axis of the drawing wheel, and the lever or bar is in an inclined or slanting position passing backwards to the driving wheel, the axle of which passes through the other extremity of the lever, which is thus made to serve as a bearing. Between the driving axle and the engine is introduced a spring, for the purpose of rendering the movement of the engine easy and free from jolting. A similar arrangement may be made with two or more levers at each side of the engine similar to the above described.

The frame of the wheel is constructed of wood or of iron, or of both; it is furnished with a metal tyre, roughed or indented to facilitate adhesion to the surface over which it travels, and of sufficient width and diameter to promote easy locomotion on an impressible surface; the annular toothed circumference is of iron, or of other metal, and may be manufactured in one piece or in segments; the teeth may be placed on the inner or on the outer circumference; in the former case the driving spur is placed between the toothed rim and the axle of the driving wheel. A shackle chain is used to communicate rotation to the driving wheel; the teeth on the rim are suitably constructed for that purpose; this annular toothed wheel is firmly secured by bolts to the frame of the driving wheel.

The connecting lever or link is a wood or iron bar furnished with a bearing at each end, through one of which passes the axle of the driving wheel, while the other is secured to the spindle of the driving spur, keeping the two wheels in gear; its length is varied according to the distance between the axles of these two wheels. The driving spur is a small toothed wheel secured to the end of the spindle; it communicates motion to the driving wheel, either directly, or by the aid of a shackle chain. The spindle is provided with a clutch, so that it can be thrown in and out of gear with the motive power; this is to facilitate turning the engine, it being necessary in a short turn to liberate one wheel from the influence of the driving power. On each side of the engine is placed a slide, or guide, fixed to the frame of the engine, through which the connecting lever or link passes, the purpose of which is to keep the upper portion of the engine, when subjected to a side inclination from swaying on the axle, and to keep the bearings of the lever from any strain; the slide is of sufficient length to allow the lever an up and down play of at least six inches at that extremity which secures the axle of the driving wheel. A spring may be placed between the axle of the driving wheel and the weight of the engine, and is secured to the framework of the engine, but not necessarily to the axle, or *vice versa*. A shackle chain is used to give motion from the driving spur to the driving wheel when that is not effected by direct communication. A break wheel is keyed on to the spindle of the driving spur, to which pressure is applied by a break when the speed of the engine is to be checked; the spindle rotates in suitable bearings fixed to the framework of the engine.

CURTIS'S APPARATUS FOR ASCERTAINING FARES AND DISTANCES TRAVELLED BY VEHICLES.

The accompanying engravings illustrate an invention recently patented by Mr. W. J. Curtis, of Holloway, for an apparatus for ascertaining the fares and earnings of public vehicles. The invention relates to a novel mode of checking the receipts of and determining the fares of passengers in public conveyances. In adapting the invention to a cab or omnibus, the patentee provides a packet of cards having on their face a graduated dial, numbered and representing distances in miles, half miles, and quarter miles, if necessary. Each omnibus passenger or hirer of a cab will receive one of these cards on entering the vehicle, it having been pierced by a punch to indicate a starting point on the dial. On leaving the vehicle the card is to be again pierced, and the distance between the two nicks in the card will show the distance traversed. The punch will, however, when making the second nick, which indicates the termination of the passenger's journey, strike out a portion of the card, and discharge it into a receiver, which is accessible only to the proprietor of the vehicle. This punched-out portion will have a counterpart

CURTIS'S APPARATUS FOR ASCERTAINING FARES AND DISTANCES TRAVELLED BY VEHICLES.

FIG. 1.

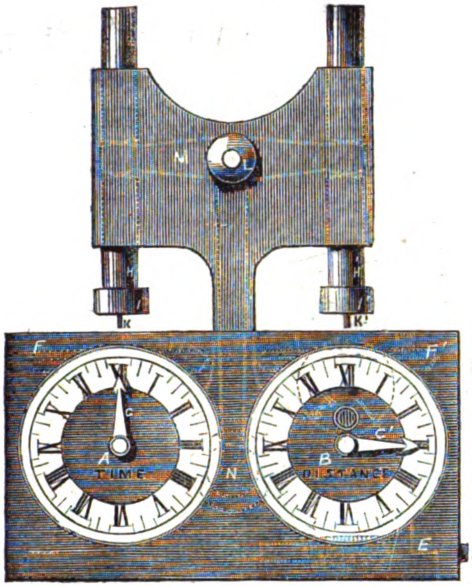


FIG. 2.

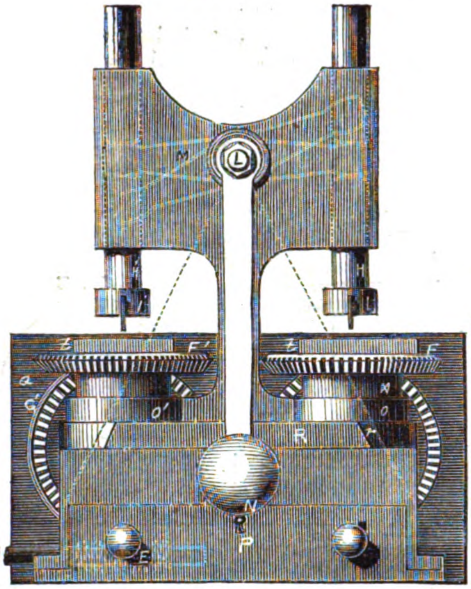

FIG. 3.

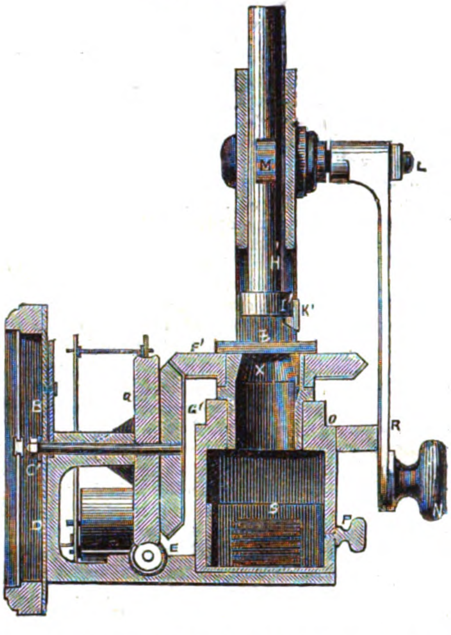


of the nicks retained by the passenger, and will, therefore, show the amount of the fare chargeable to the passenger. The manner in which this is attained is as follows:—A small rotating table is provided mounted on an open tube, and rotation is given to the table by means of a worm wheel and worm, the worm shaft being driven from one of the carrying wheels of the vehicle. The amount of axial motion the table will receive will therefore be relative to the distance run by the vehicle. If thus the relation be such that the graduated card when placed on the table would indicate by its rotation under a fixed point the distance run, it will be understood that the nicking of the card, as above explained, will give an accurate measurement of the distance travelled. The rotating table is fitted with a recess to receive the card in a given position, and above it is placed a cylindrical punch, fitted with a projecting knife blade. This punch is worked by a hand lever, and when forced down to give the first nick to the card a stop will prevent the punch from descending further than is requisite to bring the knife blade into operation. When the card is next applied to the rotating table, the duty of the omnibus conductor or cab driver will be first to draw back or otherwise prevent the action of the stop, and then to depress the lever. By this movement the punch will cut a second notch in the card, and then strike out the centre of the graduated dial, forcing it into the tubular receptacle below.

In some instances a rotating dial is mounted in the vehicle (with a fixed pointer) corresponding to that on the card. The dial in this instance is connected with the gearing which drives the rotating table, and thereby ensures a corresponding rotary motion between the dial and the table. The use of the rotating dial is to afford passengers a means of checking the marks on their card when entering and leaving the vehicle.

In vehicles hired by time the rotating table may be operated by clockwork, and the dial on the card to be pierced may represent a clock face. The distance between the nicks made on entering and leaving the vehicle will in this case show the time consumed in the journey.

Fig. 1 shows a front view; fig. 2, a back view; and fig. 3, a section in the line of the axis of the distance indicator.

A is the dial of the clock, the movement of which may be similar to an ordinary clock movement. On the axis of the fusee is fixed a mitre bevel wheel G, which gears into another mitre bevel wheel F, working loose on the upper part of the vertical bolster X fixed firmly vertically in the box O, O^1; H is a vertical punching machine, similar to those in common use for stamping paper, the piston being raised and depressed by the lever M and handle N. The punch K is connected with the lower part of the piston in the usual way, and the marker K, like a thin chisel or knife, is firmly connected with the punch. The dial bevel wheels and punch connected with the distance indicator are the same as those for the time or clock indicator just described, the movement being effected by means of the worm wheel Q worked by the worm E connected with one of the carriage wheels, the divisions on the distance dial showing the miles and parts of a mile travelled by the carriage, as the time dial shows the time occupied by the journey. Upon the axis of the worm wheel Q is a pinion working into a cog wheel five times its diameter, upon which divisions are formed and figured, shown by the dotted lines and figures behind the distance dial in fig. 1. As the figures pass the hole shown in the dial, the number of miles travelled in a day or any determinate time can be noted. The mitre wheels fixed upon the axles of the clock and distance dial hands gearing into the horizontal wheels F, F^1, the revolutions of the whole perfectly coincide, so that cards printed with a dial and kept in the horizontal wheels, the same numbers and divisions on the cards will point to a fixed point in the same way as the fixed numbers or divisions on the dials are pointed out by the moving hands or pointers C, C^1. The cards are kept accurately in their place by being dropped into the frame t, t^1, fixed on the back of the horizontal wheels, and one corner being cut off the cards will only fit in the right way, and no possible mistake can ever arise whether the distance or time side of the card be used, and by printing the cards no error can arise in working the machine. A drawer is placed under the punches to receive the centres of the cards cut out by the punches, which drawer being only accessible to the proprietor of the carriage the centres of the cards or vouchers cannot be tampered, with by the driver. A notch is left in the upper part of the fixed bolster in order to allow the markers K, K_1, to pass through the cards. On the face of the box a projection R is formed, against which the back of the handle N works, and stops r, r^1, are placed (as shown in fig. 2) to limit the movement of the handle, thus regulating the stroke of the punches when the card is to be marked by the chisel K, K^1, in the first instance; but when the longer stroke is required for the last operation to cut out the centre of the card, the driver pulls the handle forward by means of the nob N, when the handle will be sprung outwards, and caused to pass the stops r or r^1, and the stroke lengthened as may be required. D is the dial plate, both dials being shown upon one plate; they may be detached, if preferred.

The "modus operandi" is as follows:—The cards placed upon the horizontal wheels or tables F, F^1, turn round in the same time as the hands of the clock and distance indicator, and consequently any point of the dials pointed out by the hands corresponds with a like point under the chisel or knife of the punch, so that when a passenger enters the carriage, a card being placed in either of the frames t or t_1, and the handle N drawn right or left by the driver until it is stopped by the projection r or r^1, the chisel will cut through the card, thus marking the time or distance at starting, then when the journey is ended, a second punch being given by the chisel denotes the time occupied or distance travelled, thus denoting the fare payable by the passenger, but in the second operation the punch is made to give a longer stroke, so that the round part I or I^1 is made to punch out the centre of the card, which dropping into the drawer S of the box, and having upon its outer edge the cuts of the chisel, remains a voucher to the proprietor of the fare received and distance run by the carriage when the fare is determined by distance only. If it should be desirable to ascertain both time and distance, by nicking the card in the time frame and then turning the card upside down and nicking it in the distance frame at starting, when the journey is ended nicking the card in the distance frame and then nicking it in the time frame, one side of the card will show the distance travelled, and the other the time occupied in travelling. The passenger by inspecting the dials, or by taking the card upon starting, and handing it to be nicked by the driver when leaving the coach, can never suffer any imposition.

A person at Toronto has constructed india-rubber mailbags with the mouth compressed by screws, so that the bags are water-tight, and will float when full of letters and effectually preserve their contents. It is stated that they can be made at much less cost than the leather bags, and will stand far more wear and tear.

TRANSFORMING CIRCULAR MOVEMENTS.

MR. A. L. THIRION, a Roman Catholic clergyman, of Namur, Belgium, patented in England, in the year 1858, the following method of communicating circular motions:—

The invention consists in connecting the shafts of wheels to which motion is to be communicated, first, by means of a number of circles or rings cut through and connected together end to end, in such manner that the whole will form an elastic spiral, for the purpose of communicating motion from one shaft to another not in a line with the same. Or, instead of the aforesaid circles, a number of spirals are employed, formed of wire, folded one over the other so as to form but one. Secondly, by means of a number of circles or rings (the first of which is attached to the driving shaft) turning upon a curved or semicircular axis, the circles being connected to each other by bands in such a manner that when motion is imparted to the first circle, it actuates the second circle, and so on, through the whole number of circles employed when the motion is transformed to the desired wheel or shaft.

Fig. 1 represents an horizontal axis A, A, to which is attached the first circle of the spiral S, S. Motion being given to the axis A, A, it follows that all the circles composing the spiral turn at the same time, and communicate their motion to the axis B, B, and consequently to the wheel R, R. One half revolution being completed, that part of the spiral at S¹, S¹, will be found at S, S, and *vice versa*. Said spiral is made supple, whilst at the same time it should offer a certain amount of resistance. The necessary degree of suppleness or elasticity is obtained by means of flattened or sheet iron (fig. 3), and the amount of resistance obtained by giving to the circles cut out of sheet iron a certain width, as shown at L, L, fig. 3. The circles are uniformly cut according to the line L, L, and joined end to end, so as to form but one piece or spiral. A number of spirals formed of wire, rolled one over the other, so as to form but one, may be used. To prevent the circles spreading out unequally, they can be connected at certain intervals by bands or wires.

Fig. 2 represent several circles turning upon a curved or semicircular axis. The first circle actuates the second, to which it is attached by a band C, C; in like manner the second actuates the third, and so on until the last. It is not important that these circles should be entire, it being sufficient that they should turn in the axis.

ANTI-INCRUSTATION COMPOSITION.

THE incrustation of boilers is a matter just now engaging much attention, and the usual result shows itself in a multiplication of special patents.

Mr. Alexander Delrue, of Dunkirk, France, has taken out a patent for compositions to prevent and remove incrustations. The compositions are composed entirely of vegetable matters, and are prepared by dissolving or infusing in hot water the bark of the oak and pine as well as the leaves of the sumach tree ground and reduced to the state of a coarse powder; this decoction is concentrated to a density of about 10 deg. Beaumé, and to it is added a quantity (say from 15 to 30 per cent.) of cream of tartar (bitartrate of potassa) and spirit of turpentine. In employing this liquid to prevent incrustation in steam boilers, a quantity of it is introduced from time to time into the steam boilers, the quantity of the liquid required varies according to the capacity of the boiler, three pints of the liquid being generally sufficient for every thousand pints of water in the boiler to prevent incrustation forming for about ten days.

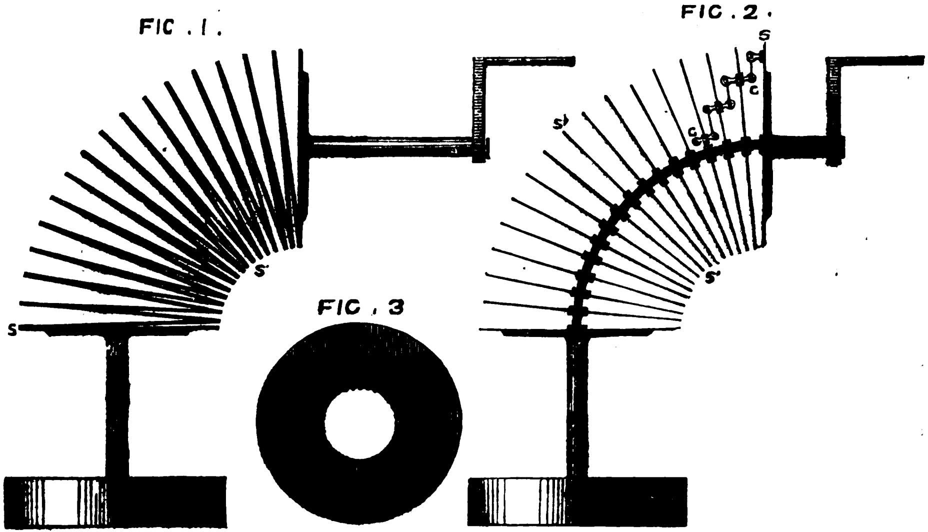
TO CORRESPONDENTS.

Correspondents who wish their manuscripts to be returned are requested to state this.

We beg our correspondents to choose initials, rather than general signatures such as "Constant Subscriber," or "Reader," &c.

A. S.—Glass gauge tubes may be cleaned by washing in dilute sulphuric acid, and then rinsing them in pure water.

THIRION'S COUPLINGS.



D. T.—"Molesworth's Pocket Book of Formulæ" would probably suit your purpose.

H. R. M. (Plymouth).—It is very probable that the cement would crack by the jar occasioned in nailing on the metal sheathing. It is also not unlikely that a solution of caoutchouc applied to the ship's skin, or to the back surface of the wood sheathing, would be of good effect; but it is impossible to pronounce an opinion upon questions that depend so much upon experimental conditions. The use of a solution of india-rubber would of course be very expensive. You will find an abstract of a paper read by Mr. John Grantham, "On the Hulls of Ships and Fouling of Ships," before a meeting of the United Service Institution in our numbers for Nov. 15th and Nov. 22nd, 1861, pages 328 and 341. In the second part of this paper, pages 341 and 342, you will find his peculiar plan of sheathing for ships fully described by the gentleman himself.

F. G. would do well to study the amenities which are generally recognized amongst journalists before he writes.

D. E. (SUBSCRIBER.)—The data you give are not sufficient to make a complete estimate; but, it is well known that *one* vertical saw blade of the description you are using consumes one *actual* or indicated horse power per hour in cutting at least 45 superficial feet of soft wood per hour. We do not know the amount of work you want to turn out, nor the state of the sawing apparatus, nor the distance from whence the power has to be conveyed, &c., &c., but three-horse power ought to be amply sufficient to do your work. If you hire the surplus power of some engine, you could exactly ascertain the power you consume by means of an indicator.

G. C. P. and J. B. B., whose communications on "Silicate of Potash" appeared in our numbers for February 27th, and January 2nd respectively, are begged to communicate with T. S., 7, Pear-street, Ecclesall-road, Sheffield.

W. F. (Tenby, South Wales).—Have you calculated the amount of horse-power required to propel an ordinary vessel at "a speed of thirty miles per hour"? We greatly fear that you are pursuing some ingenious "*ignis fatuus.*" It is difficult to advise an inventor as to the means of effectually bringing his scheme into notice, particularly, if, as you state, you have already shown it in the proper quarters. If you like to forward us a clear and concise drawing of your invention, and a similar description, we will publish it *pro bono publico*, on finding that it is meritorious and novel. We will return your communication if so desired.

T. G. C. (Bristol).—Your particular arrangement for "fastening the reins to the spoke of the hind wheel of a vehicle nearest the ground, to stop the animal by the strain on the bit," should he attempt to start in the absence of the driver, seems ingenious and novel, as far as we understand it. We would always advise the making of a sketch, in order to render any mechanical scheme completely intelligible. It is obvious, however, that such a plan would not be applicable to a spirited horse.

AN ATLANTIC TELEGRAPH.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

SIR,—In my previous letter it was shown that, in the peculiar circumstances therein stated, it is now the duty of Her Majesty's Government to form the first telegraph from Britain to America. The question which it is proposed on this occasion to consider is, Where should the line be laid in the ocean—whether along the bottom, or near the surface?

To lay the cable along the bottom of an ocean reaching to more than two miles in depth, and of such great breadth—whichever route should be chosen—is most objectionable. The utmost uncertainty as to the suitability of the bottom for the cable; the thorough inaccessibility of the cable laid at such a depth for repair or otherwise; the enormous pressure of the superincumbent mass of water upon the cable, are most convincing reasons against laying the cable along the bottom of the Atlantic, if that course can possibly be avoided.

After reflecting on these evils and the means of their avoidance, I proposed, some two or three years ago, that a telegraph cable of slightly more specific gravity than salt water should be suspended near the surface by means of, say, five or six buoys, each placed at a due interval along the route from Britain to America, and so anchored as to approach within 20 or 30 fathoms of the surface, at or about which depth it is believed the cable and buoys would be out of the way of surface commotion of *every kind*. I also then showed that in the open ocean, at a distance of a few miles from land, there are no tidal or other currents, excepting surface currents caused by the wind, and which only prevail a few fathoms down. The cable, where it left and approached the land, would be adapted to and laid along the bottom of the sea,—as land is the real cause of, and is surrounded by, tidal and other currents, excepting in so far as currents are occasioned by the wind on the surface, as above-mentioned. By adopting this course, the nature of the bottom, except at the shore ends, would be a matter of no consequence; the cable would be quite accessible; the pressure of a great superincumbent mass of water, with all its evil consequences, would be avoided; and, in addition to all these advantages, the cable itself would be more cheaply constructed and easily laid in consequence of its lightness.

I am aware that these views as to the non-existence of *under* currents in the open ocean are opposed to Maury's views in his book "The Physical Geography of the Sea;" but that book, I feel bound to say, after much investigation and consideration, is, so far as such currents are concerned, a mere romance—full of groundless assumptions and false analogies—and utterly opposed to all sound scientific reasoning, as that can only proceed on a basis of direct positive fact. The analogical fallacy which seems to have originated, and which vitiates, all his views on the subject, is grounded on the idea that currents must prevail to as great an extent in the liquid ocean as in the gaseous atmosphere. But that is a complete *non sequitur*, as any one who has paid sufficient attention to these two different states of matter, and their action, must be aware.

Since this system of surface telegraphy was proposed, I have seen no reason to abandon or modify it. On the contrary, I have since come to the knowledge that Mr. Wartman, of Geneva, has established that pressure diminishes the conducting power of a copper—and, doubtless, also of every other kind of wire—a fact which renders the adoption of surface telegraphy all the more imperative, for the enormous pressure of water two miles deep, and along many hundreds of miles, and that constantly upon a telegraph cable, must be most pernicious, and fully accounts for the failure of the former Atlantic Cable.

"An Old Sailor" recently criticised Dr. Wallich's plan for ocean telegraphy, lately published in your columns, and which plan it humbly seems to me is only valuable in so far as it agrees with the proposition now submitted. His criticisms unfavourable on the points of difference appeared to me to be well founded. I would take it as a favour if he would also criticize the present proposition. But he must *not assume under* currents to exist in the open ocean at and beyond a distance of, say, forty or fifty miles from land, unless he actually knows that they do exist.

Groundless assumptions have always been the bane of science, and, consequently, of advancement. And I think it will be admitted, that if no such under currents exist, all the mechanical arrangements involved in the present proposition would be accomplished with comparative ease, and would work successfully. H. K.

Edinburgh, March 18, 1863.

THE FRANCE AND ALGIERS SUBMARINE CABLE.

Sir,—From the very deep interest which has always been felt for this cable; owing to its being the only really deep sea telegraph which has, up to the present time, been a lasting success, I have been induced to inquire very minutely into all the circumstances connected with its failure, in order that they may be fairly estimated and considered in future.

The cable was commenced, and successfully laid from Algiers as far as the Island of Minorca, in September, 1860, and worked it in connection with the Spanish lines until September, 1861, when the second section, to Port Vendrees in France, was completed, and joined up—the entire length requiring but four ordinary battery cells to work the constant day and night stream of messages, the receipts from which, even in the comparatively short time the cable has been at work, have more than repaid the capital expended upon it.

On the 25th of November, and again on the 13th of December last, there were very heavy gales in Algiers, accompanied by lightning; and two separate faults were reported to the French Telegraphic Administration, and greater battery power was used to try and work through. The paddle brig-of-war "Brandon" was detailed with M. Ailhand and his staff to try and repair it. Their first tests indicated the fault near Port Vendrees, where it was lifted and cut; but their tests then gave it near Minorca, where M. Ailhand again lifted the cable, and cut it, carrying the end of the Port Vendrees section into Minorca, and dropping the end of the Algiers section into the sea. Their further tests then gave the fault near *Algiers*, where the cable was underrun to a distance of 2¼ miles from the shore in 85 fathoms water, until they reached the main hemp and steel cable. After this the water deepened very rapidly, and they cut the cable, joined it up again and dropped it, as their appliances would not allow them to underrun further. The French Administration then applied to Messrs. Glass, Elliott, and Co., to allow that firm's steamer, the "Hawthorns," which was then in the Mediterranean, to proceed to their assistance; and on her arrival at Algiers on the 29th of January, Mr. Canning adopted the following course of proceedings, at the wish of M. Ailhand:—That the "Hawthorns" should go to Minorca to find and test the end of the Algiers section, and to pick up some cable there, and that the "Brandon" should go to Toulon for more cable, so that on their return to Algiers the "Hawthorns" would have sufficient cable on board to lay in a new piece should she reach the fault off that place.

The tests by Mr. de Santy from the Algiers end indicated that either a break in the cable, or else the copper was exposed at a short distance from the shore.

The "Hawthorns," when at Minorca, found the end of the Algiers section about 1¼ miles nearer the shore than the position pointed out by the "Brandon;" and the iron cable recovered which had been underrun by that vessel had evidently been handled very injudiciously, and not as a delicate submarine cable ought to be used. The tests from Minorca showed a second fault about 90 miles towards Algiers.

Returning to Algiers, the "Hawthorns" grappled the cable off there, underran it to the junction with the main cable, cut it, and commenced to pick up towards the first fault, but only 150 fathoms after the splice made by the "Brandon" had been lifted, when the end of the cable came up, without having shown the slightest indication of strain on the dynamometer, and being quite slack. Depth of water 85 fathoms, and soft blue mud bottom.

The end being carefully examined, the outer wires proved in very good preservation, and from their appearance had evidently been broken by the "Brandon" in making the previous splice, as they were drawn in—like a kink, and the cable had been dragged a long way to the eastward of the course in which it was originally laid.

As the soundings gave a depth of 260 fathoms only half a mile further out to sea, and as the weather at this season is very much against these operations, it was decided that the attempt to reach the fault for the present should be abandoned.

From the faults having shown themselves immediately after heavy gales with lightning, it is the general opinion that lightning has been the cause of failure in this cable, especially as there were no lightning conductors in circuit with the cable and land lines; as, even for the short time the cable was landed at Minorca in 1860, during a violent storm of lightning, the conductor, which at that time was fortunately in circuit, was fused, and had it not been for this safeguard, the cable would at that time have been seriously damaged or rendered useless.

Taking the whole circumstances into consideration, I am led to believe that, had the ordinary precautions—lightning conductors—which are used with almost every other cable, been in circuit, the Algiers cable would have been still successfully working; or when the faults were first shown, had a vessel, thoroughly fitted with the proper appliances for these operations, been sent out, the first fault off Algiers could, we think, have been cut out, and it would then have been more than possible with the usual battery power to work through the second fault, and we should not now have to announce the loss of what we hoped was a really lasting deep sea telegraph.

The cable that has been picked up is in an excellent state of preservation, and is nearly covered with marine incrustations. The section of cable from Minorca to Port Vendrees is still in good working order, but it is commercially useless so long as the Algiers section is silent.

T.

Algiers, March, 1863.

AN ATLANTIC CABLE.

Sir,—Considerable despondency manifests itself up and down the country because of the slow progress made towards establishing electrical communication between Great Britain and America by means of an Atlantic cable, and the opinion is very prevalent that this desirable result can never be brought about by any public company unassisted by Government, or unless the executive take the work entirely into their own hands, and debit the revenue of the country with an extra half million for that purpose. This feeling is very natural, and it is useless to ignore its existence. The project of a second Atlantic cable *has not* met that hearty response which some people calculated on, and which, at first sight, one would feel bound to say it merits. There is unquestionably an indisposition on the part of capitalists to embark in the enterprize which is by no means agreeable to the over-sanguine; but it is worth while to investigate the cause of this. It may be attributed principally to two causes, one of which, however, would be comparitively inoperative were it not for the other. First, there is the disastrous failure of the old cable, and, secondly, the position assumed by the Atlantic Telegraph Company as at present constituted. With respect to the first consideration, ruinous and disheartening as the failure was, it yet practically demonstrated that the thing was feasible, and proved beyond question that what was then attempted, not altogether without success, would, at no distant date, be an accomplished fact. So that, in reality, it may be almost assumed that the element of confident hope preponderated, and, consequently, the opposite element, whereby the work was so lamentably retarded, was to be deemed only temporary. Of course it would be going too far to say that this feeling had become innocuous, but it was fast dying out, and would ere this have been ineffectual in hindering a renewed attempt, were it not for the anomalous characteristics of the Board of Directors of the Company now in process of formation, and which we have to consider as the second and principal cause why men of standing look shy at the concern.

It is, to say the least, an unjustifiable anomaly for any company to issue a prospectus soliciting capitalists to take up shares without condescending to say of what the bill of fare will consist. The Atlantic Telegraph Company should have been prepared with full particulars as to the description of cable they proposed to lay at the onset, and thereby have secured that implicit trust and confidence which is necessary should exist: every man interested in the scheme would then have been able to decide for himself as to the prudence of making an investment by taking up shares in the company, inasmuch as it would enable him to judge if the cable proposed was, or was not, in accordance with the teachings of electrical and telegraphic science; and if not in accordance therewith, there would still have been the chance left, on the one hand, to stipulate that the cable should combine in its construction the results of acquired experience up to this time, taking for its basis the conclusions of the Government Commission; and, on the other hand, the Atlantic Board could have descended from their pedestal without loss of dignity, and with perfect ingenuousness, to meet the requirements of the case as dictated by common sense, common experience, and the common interests of both. But the Atlantic Company have failed to do this; and I can, therefore, only repeat that their position is anomalous; nor have their subsequent proceedings been reassuring; how then can we wonder that they have not received that support which sanguine, but superficial observers, think they should have received? In lieu of what they should have performed, what have they done? The discordant elements which make up their scientific consulting committee will not beget the confidence that is wanting. Here are doctors of first-class eminence, and professors of world-wide celebrity, appointed to sit in conclave upon—a difficult problem, as some would make out, but which in reality is—almost the simplest matter under the sun, and quite within the range of the most ordinary electrician or telegraphic engineer. Seeing that the problem is already solved, and simply requires its fundamental points to be acted upon in all their entirety; in saying thus much, I neither undervalue the importance of cable construction, nor do I depreciate the deserved popularity and just eminence of men of whom this country and this age may be justly proud. But what has this committee done during the months that have elapsed since they were appointed? No conclusion has as yet been come to, and things remain in *statu quo*, and are likely to remain so for who shall say how long?—for are not these men, with all their celebrity, influenced some this way, some that, by motives which comport not with their dignity, nor the side they individually show to the world, nor yet the gravity of the subject they have in hand? I might here pause to inquire for what purpose was the committee appointed? Were its members really chosen that by their deliberations a first-class cable should be secured?—if so, they have had ample time, the task being not much more difficult than a simple sum in simple addition. Or rather was not their appointment a ruse, a make-believe, a promise of fine things to come—in short, a substitution of a sham for the reality?—if so, the cash might be got together in that way, without the directors being under the disagreeable necessity of binding themselves to any course in their choice of a cable which should run counter to their prejudices and, what is more, their interests. The opinion and counsel of such men as constitute this committee should be invaluable, and doubtless is, if taken individually, and proper discrimination were observed in comparing, sifting, and applying the same; but they occupy a wrong position for all that; or rather, perhaps, it is a position which should have been held prior to any prospectus being issued; and instead of having to announce the appointment of such a committee, the Atlantic Board should long since have had to record the result of its cogitations by giving a minutely detailed description of the cable recommended by the eminent conclave. And now there is but one thing that as wise men they can do, and that is to decide forthwith upon the style of cable they mean to adopt, and let the public judge if it be worthy of their support or not. So long as this matter is kept in the background, what proof have we that there will not be a repetition of some of the old blunders—that the results of the Government Commission will not be utterly ignored, as well as subsequent advances upon that, seeing that there is a large monopolized element mixed up with this body which is inimical to success, or at all events inimical to the manufacture of a cable commensurate with the requirements of the case and made in conformity with the advancement of telegraphic science. There are other minor causes which might be adduced, each contributing its quota to bring things to a dead-lock; these will readily suggest themselves to the reader whose perusal has kept pace with what has already been written upon the subject. But there is one we may just glance at. The securing of a proper cable is, of course, of paramount importance, and is a matter of the greatest moment; the submergence of that cable is only second in importance, and is a point upon which too much attention can scarcely be bestowed; and yet we have no intimation whatever from the directors of this company that they have taken any steps to secure a more efficient method of submersion than the wretchedly ineffective mode hitherto pursued, and according to no mean authorities is simply submitting the cable to a vigorous martyrdom, of itself sufficient to render useless the best cable ever manufactured. The organs of the Atlantic Company do not forget to boast of the eminent men of science called into its councils; but how is it that the nautical element is excluded? This latter, is, if anything, of more importance than the former. The manufacture of a good cable—thanks to the Government report and other means of enlightenment—is now a tolerably simple matter, although electricians would fain make it appear as complicated as a simple question of right and wrong after it has filtered through lawyers' brains, barristers' wigs, and courts of law; not so the submergence of a cable; this is a point little understood, and no intelligible and rational method of submersion will ever be hit upon that does not emanate from a seaman; then why are experienced seamen excluded from the councils of the Atlantic Telegraph Company, since no man incapable of managing a vessel in fair weather and foul ought to be entrusted with the laying of a cable? Is this flagrant omission likely to contribute to the confidence that is lacking? They who are careless to secure confidence by obviously right and legitimate means, ought not to possess it; and the case before us is a proof that they do not.

It cannot be gainsaid that, with the exception of an abundance of words to puff the thing into notoriety, nothing whatever has been done to confirm the vague and unsatisfactory promises made. The result is an indisposition on the part of capitalists to make up the sum required ere the allotment of shares can take place. But the Board of Directors have the power in their own hands to partially restore this want of confidence if they will only adopt a course opposed to that hitherto pursued, and manifest by deed as well as word that they are desirous of securing a good cable, made of the best quality of the most efficient materials, and by those whose specimens experiment has proved to be unexceptionable; that they from henceforth forego antiquated prejudices and petty interests, and abjure utterly all alliance with monopoly and every other noxious influence; that they will not entrust men inexperienced in, and innocent of, the smell of salt water to lay their cable when made by means of the barbarous expedients for submersion used hitherto; but will esteem experienced nautical men as indispensable to their councils, as giants in electrical science are in other respects. But failing to do this, things stand an excellent chance of remaining just where they are, nor can we regret that they should continue so, looking at the matter calmly and dispassionately. It is simply a choice between two evils: for affairs to continue as they are is the lesser evil, as the only other alternative is a certain risk of inefficiency, if not failure—by no means a desirable consummation to those true lovers of progress who desire not the prostration for perhaps another half century of submarine telegraph enterprise.

Medical, at 8.30 p.m.

TUES.—*Inst. Civil Engineers.*—"On Structures in the Sea; with a Description of the new Albert Harbours, Greenock," by Daniel Miller, Esq., at 8 p.m.

THURS.—*Linnæan Society*, at 8 p.m.
Chemical, at 8 p.m.

Gossip.

One of the largest merchant vessels ever borne upon the waters of the Tyne was launched on Saturday last, from the extensive iron-shipbuilding yard of Messrs. C. and C. M. Palmer, Jarrow. This vessel, the "Georgia," is the first ship of the three ships that has been completed; the others are in a state of forwardness. We understand it is the intention of Messrs. Palmer to launch the last of the three during the visit of the British Association to Newcastle. The "Georgia" is of the enormous burthen of 3,000 tons. She is capable of stowing 8,000 bales of cotton, and it is calculated that when fully loaded she will not draw more than 17 ft. of water, so as to suit the depth of water on the bar of the Mississippi. She is marked, however, up to as many as 24 ft. on the stern. Her length is 325 ft., beam 41 ft. We may mention here that the firm are under contract to build seven vessels, each of them 30 ft. longer than the "Georgia." She has a splendid full poop and top-gallant forecastle: the former is 90 ft. long, and the latter 50 ft. She is fitted up to carry 70 saloon and 200 second-class passengers. The saloon will be handsomely fitted up. She will carry a crew of 120 persons of all classes. She is roomy between decks, and the depth of hold is 30 ft. She will be fitted with a screw. Her engines will be nominally 300-horse power, constructed on the surface condensing principle, and fitted with feed heaters for the feed water and superheaters for the steam. Her engines when fully working will indicate about 1,200-horse power, and it is calculated they will propel the vessel at the rate of 10½ knots an hour. The boilers were designed and constructed under the immediate superintendence of Mr. F. C. Marshall, manager of the engine department of the works. She is fitted with a lifting screw, so that she may proceed without impediment when under sail alone. This vessel, together with her machinery, has been constructed under the inspection of Mr. John Jordan, surveyor for the Liverpool Underwriters' Association. This association has been commenced with a view of classing such ships at a higher rate than heretofore, so as to fully recognize the qualities of iron ships. The "Georgia" will be classed 22 years A 1.

H. Roper, of Roxbury, Mass., has invented and completed a steam carriage, which, according to report, subserves the ends for which it was made. A recent trial of this innovation upon the "old style" was very successful; it passed through Boston, and, meeting a car on the horse-railroad, turned off the track, and went around the car, with as much ease as if drawn by a horse. On a smooth road or on the rail, with sixty pounds of steam (the usual amount), the carriage can be run at the rate of twenty miles per hour. The weight of the carriage is 650 pounds.

A prospectus has been issued of the Patent Ventilating Granary Company. The object is to work certain patents granted to Mr. A. Devaux, in 1856, for improvements in the construction and fittings of granaries, and the board of direction comprises several representatives of firms largely connected with the corn trade.

Letters from the Upper Canada oil springs state that a well, which some time since ceased to flow, has again commenced spouting, and now yields from 300 to 400 barrels a day. A large quantity of oil is also being taken from the different wells by pumping; so there is no fear of any present failure of the supply. The inhabitants of the oil district are about to sink what istermed a "test well," in order to ascertain what quantity may be expected to flow from a greater depth than yet reached. It is intended to sink this "test well" 1,000ft., as none of the present wells exceed 300ft., in depth.

A correspondent of the *Engineer* says the great bridge over the Niemen, at Kowno, on the branch of the Great Russian Railway from Vilna to the Prussian frontier, has not attracted in England the attention which it deserves. This fine structure has a space of 129 sajenes or 903 ft. between the abutments, and there are besides two supplementary spans of 5 sajenes each, to assure the communications on the two shores of the river. The bridge is composed of four principal spans, resting on three intermediate piers and two abutment piers. The piers are formed of strong cast-iron tubes 8½ ft. in diameter in the interior, and sunk in the bed of the river by means of atmospheric apparatus to a depth of 5 sajenes or 35 ft. The sinking of these tubes was commenced in 1860, and they were completed in time to receive the girders, which were hoisted to their place with much pains and difficulty, but happily with great success. The structure was finally completed and made available for traffic March 1, 1862. At least 100 iron bridges must have been erected on the 1,010 miles of railway which compose the Great Russian system; but none of them approach in importance the great work over the Niemen, which was crossed fifty years previously in a very different fashion by Napoleon I.

An attempt made at Portsmouth to coat the armour-plates and their bolts with zinc by a French patented alkaline process has failed. A proposition has, however, now been laid before the Admiralty by a Mr. Walenn, a London chemist, to coat iron of any size, from a ship's bottom itself as one whole to a single bolt for the armour-plate, extent of material or shape being no objection, with a deposit of metal, such as brass or any other alloy, as thin as thick in substance as may be wished, with a bright, hard, enamelled surface. It would be at once seen that this would supply what is chiefly wanted—the means of preventing the oxidation of ships' armour and bolts and the fouling of iron ships' bottoms. Mr. Walenn has been directed to proceed to Portsmouth Dockyard to inspect the existing arrangements of baths and batteries now adopted there, and to send in to the Admiralty a special report, with accompanying estimates of his proposed plan of electrotyping.

In our last work on machine belting, we omitted to notice that Messrs. J. Moulton and Co., of Bradford, Wilts, were the oldest manufacturers of machine belting in the kingdom, and that they were the first to make belting on the American plan in this country.

The Admiralty have made the necessary arrangements with Captain C. P. Coles, R.N., for the construction of a seagoing shield ship, according to his plans, the aid of a professional draughtsman being accorded to Captain Coles by the Admiralty to assist him in carrying out his ideas. The central gun battery, shield, or turret principle has hitherto lain under a cloud to a certain degree, owing to the impression which had been widely disseminated that such a vessel could, under no circumstances, be equal to a broadside gun ship as a seagoing vessel for long cruises—say to the Pacific or China. Captain Coles has, however, always asserted the contrary, and has maintained that iron ships constructed and armed on his plan were not only better fighting ships than any broadside gun ships, whether of wood or iron, but that they would also be better sea boats under all circumstances of wind and weather.

A recent correspondent of the *Scientific American* contains a rather extraordinary suggestion for defending harbours. "I herewith, he says, give you an idea which may or may not be practicable; of this I leave you to judge:—Supposing the entrance into a harbour to be narrow, and a good fort or other stronghold to be in the neighbourhood, with a convenient place for a steam engine; from this lay down pipes of from three to six inches in diameter, directly across the channel where the vessels have to pass; the pipes are provided with several valves, so that no water can enter them. When required, fill the pipes with native distilled *coal oil* or other hydrocarbon liquids; then apply a force pump at the end nearest to the fort and force through the pipes a continued stream of oil, which, by the pressure, opens the valves and discharges the liquid oil. This oil being lighter than the water floats to the top, and can then be set on fire, either by Congreve rockets thrown from the land or by a preparation which, together with the oil, is forced through the pipes and would ignite when coming in contact with the air. There may be also forced through the pipes a quantity of small explosive shells which would do some service. The ignited oil will not only set the combustible parts of the ship on fire but will create such a dense and unpleasant smoke as to blind and suffocate officers and crews on board the vessels. I have been once in the midst of the fire and smoke of burning petroleum; and therefore I know that any one who has once experienced its horrors will never wish to be surrounded by it a second time."

At a conference held some days ago of those interested in Belgian railways, it was resolved that a gold medal of the value of 400f. (£16) should be given to the author of the best essay as to the means to be adopted for the improvement of traffic on the lines in this country, more particularly as to the manner in which the reciprocal obligations of the proprietors of railways, and of those who make use of that mode of conveyance either as passengers or as the forwarders and receivers of goods, should be most justly fulfilled; also as to the proper relative proportions of receipts and expenditure in the working of railways; and, finally, as to the influence which the rate of charge has on the conveyance of goods by rail in Belgium, both as to the length of the journey and the system of tariff that should be preferred. The essays must be sent to the office of the Railway Conference, 15, Galerie du Roi, in this city, before the 1st of May; and as they may be written in French, Flemish, English, or German, and all the statistical returns of the different lines will be placed at the disposal of intending authors, it is expected that there will be many competitors, so that much valuable information will be obtained, which may be turned to good account in the future management of railways in this country. It must also be admitted that, though it may be a check, it is by no means a fair way of obtaining useful hints from many who are well qualified to give them.

Uninflammable Stuffs.—On this important subject the French Academy of Sciences has received a report from MM. Payen, Velpeau, and Rayer, in which M. A. Chevalier's paper, sent in to the Academy on the 25th of January last, is discussed. From this report it appears that only three salts have hitherto been found that may be successfully applied to the purpose in question—viz., that of preventing ladies' dresses from catching fire. There are many other salts that would do the same, but not without spoiling the dye, or the gloss, or the texture of the stuff, &c. Of the three in question, the sulphate and phosphate of ammonia have the inconvenience of being decomposed by the heat of a smoothing-iron; but they are applicable in those manufactures where stuffs are stiffened by the action of hot air or cylinders heated by steam. They exercise no action upon either the thread or the colour of the stuff. The phosphate of ammonia may be mixed with half its weight of hydrochlorate of ammonia. To obtain an efficacious solution, 20 per cent. of this mixture must be dissolved in water. A solution of 7 per cent. of sulphate of ammonia produces the same effect, and is therefore the most economical salt that the trade can employ. But in those cases in which the smoothing-iron cannot be dispensed with, as in linen, for instance, a solution of 20 per cent. of tungstate of soda should be preferred. To obtain the desired effect, all these solutions must be applied to the stuffs after they have been stiffened and dried, because starch is always used in a weaker solution than that required for these salts. Acid tungstates destroy the thread of cotton stuffs, like borax, alum, and other substances previously recommended. The tungstate of soda is prepared in Cornwall, where the tin mines yield a large quantity of wolfram. It costs from £12 to £18 per ton, or about 4f. per kilogramme. The sulphate of ammonia costs about £14 per ton; it is produced in gasworks, and has hitherto been used for manure. —*Galignani.*

Gun Shield and Great Gun Experiments at Shoeburyness.—Want of space compelled us to omit in our last impression the concluding portion of our report of these interesting experiments. As it relates especially to the armour of land forts, an object no less important than that of iron-clad ships, we supply the omission, and recommend the observations which follow to the consideration of public men who are devoting their attention to the great question of our national defences. It remains for us to give some account of the state of the gun-shield after the tremendous battering it underwent. Nothing but the weight and mass of the iron plates and bars of which it is composed, sustained by a strut at each end of prodigious strength, kept it standing. At some parts a triple casing of iron made an aggregate of 18 in. in thickness, which was in no part less than 12 in. The principle relied upon was solidity and weight of the parts separately and collectively. But no mechanical means were employed to connect the parts securely and strongly to each other. There was no cohesive strength in the whole. The plates and bars were piled and crossed one over the other, and pinned together with 3-inch through-bolts. This mode of fastening rendered it impossible to draw the plates up taut to a bearing, so that between the layers of plates there were intervals which, however minute, were sufficient to render excessive vibration inevitable. To this defect of structure we believe the cracking of the plates is to be attributed. The real damage to the shield may be described by one word "dislocation." The parts separated from want of cohesive force, which cannot be obtained in such a material as iron by planks overlaying each other, no matter what may be their thickness. Engineers do not trust to iron planks as railway-bridge girders. They construct girders with plates and angle bars rivetted together, producing perfect cohesion of parts, and presenting the maximum resistance of iron edgeways to the tensile strain. We are disposed to think the same principle is applicable to the construction of iron gun-shields and the sides of iron-cased ships. The real strength of this experimental iron fort is in the struts, which are made on the iron-bridge principle. From the result of Tuesday's experiments, showing the resistance of plates to penetration when backed with iron, if rivetted fastenings be applied to the entire framework, and the plates be held securely to an iron backing, we believe the defence will be too strong for the attack, and that iron armour may be made literally invulnerable. An interesting question, the fastening of armour plates, has had some light thrown upon it by the ingenious contrivances introduced in his gun-shield by Captain Inglis, for the purpose of putting the elastic and rigid systems to the test. Four plans for securing the bolts were adopted, by varying the material of the washers to the screw-bolts. Some were india rubber, some lead, some woven wire, some iron, and some were rivetted. The last two represented the rigid—the former the elastic principle. Altogether, during the experiment six or seven screw-bolts were broken; of these all but two were provided with elastic or yielding washers, and not one rivetted bolt was broken. We are far from maintaining that these results determine the question, but they are indications for other trials, and the public are much indebted to the Iron Plate Committee and Captain Inglis for the careful attention they have directed to the most perplexing branch of a most perplexing question.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

The Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

Steam Engines, &c., 2405.
Boilers and Furnaces, 2386, 2397, 2408.
Roads and Vehicles, including railway plant and carriages, saddlery and harness, &c., 2378, 2401, 2402, 2401.
Ships and Boats, including their fittings—*none.*
Cultivation of the Soil, including agricultural implements and machines—*none.*
Food and Beverages, including apparatus for preparing food for men and animals, 2374.
Fibrous Fabrics, including machinery for treating fibres, pulp, paper, &c., 2367, 2370, 2371, 2372, 2375, 2389, 2399, 2406, 2415, 2417, 2418, 2419.
Buildings and Building Materials, 2413.
Lighting, Heating, and Ventilating, 2379, 2380, 2385, 2390, 2393, 2424.
Furniture and Apparel, including household utensils, time-keepers, jewellery, musical instruments, &c., 2376, 2381, 2384, 2392, 2398, 2407, 2416, 2420, 2422.
Metals, including apparatus for their manufacture, 2366, 2400, 2410, 2425.
Chemistry and Photography, 2373, 2414, 2426.
Electrical Apparatus—*none.*
Warfare, 2377, 2395.
Letter-Press Printing—*none.*
Miscellaneous, 2368, 2369, 2382, 2383, 2387, 2388, 2391, 2394, 2396, 2403.

2366. T. Richardson and R. Allanson. *Improvements in the manufacture or treatment of articles of steel, and in the apparatus employed therein.* Dated August 26, 1862.

In order to obviate various well-known difficulties, the inventors employ retorts or closed heating apparatus, and they prefer such an arrangement as will allow of the introduction and withdrawing of the steel, or the articles of steel into and from such retorts or heating arrangements, without their being subjected to a similar decarbonizing action of the atmosphere, and also that each retort or other suitable heating arrangement shall be so constructed as that a desired uniform temperature may be maintained. *Patent abandoned.*

2367. L. Jarosson. *Improvements in machinery for bleaching or washing textile fabrics and materials.* Dated August 26, 1862.

This invention consists in bleaching or washing textile fabrics or materials by means of dry steam and machinery of the following construction:—To a suitable framing the inventor connects a series of rollers, over and about which the fabrics are passed. The lowermost rollers are placed in a pan or trough containing alkali, caustic soda, or carbonate of soda. The several rollers being set in motion, the fabrics are drawn from one roller and pass through the solution in the pan or trough, thence they pass upwards between pressure rollers, and, finally, to a winding-on roller. *Patent abandoned.*

2368. J. Rider. *Improvements in the construction of fencing posts or standards, to be used either for straining or otherwise sustaining fences.* Dated August 26, 1862.

In making such posts, poles, standards, or pillars, the inventor mostly uses sheet iron, or other thin plate, and he constructs them in section of a diamond, square, or other straight-sided figure, whereby he obtains considerable strength; also he sometimes constructs such posts, poles, standards, or pillars of triangular section, or of serrated or indented section (as fully delineated in the drawings). In making the joints of these posts, standards, or pillars, he prefers to use a lap joint, and after hammering or rolling the sheet iron or other thin plate to the form required, to close the lap joint by soldering, galvanizing, rivetting, or any two or more of these means; but he does not restrict himself to the use of lap joints. The improvements also consist in bushing the holes in such posts, pillars, or standards through which strained fence wire passes; such bushing may be carried into effect by using for the sheet iron thin plate or other piping or tubing secured in the said posts, pillars, or standards. *Patent abandoned.*

2369. A. V. Newton. *A novel construction of instrument applicable to the cleaning of windows.* (A communication.) Dated August 26, 1862.

Provisional protection has not been allowed for this invention.

2370. A. Crichton. *Improvements in looms for weaving ornamental fabrics.* Dated August 27, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2371. G. Davies. *A machine for singeing woven fabrics of cotton, wool, or silk, by means of gas or alcohol.* (A communication.) Dated August 27, 1862.

This machine is constructed in the following manner:—The main framing supports, in suitable bearings, several carrying rollers and a pair of drawing rollers, by means of which the fabric to be singed is drawn through the machine. The frame also supports two pairs of revolving iron tension bars or rollers, so arranged parallel to each other in a horizontal direction, and supported in bearings so constructed, that each pair of rollers can be set nearer together or further apart, as required. Below each pair of rollers is a gas pipe, furnished with a row of burners, so placed that the flame issuing therefrom in a vertical direction passes between the pair of revolving tension bars or rollers, and singes the fabric passing round each of them simultaneously, so that each row of flame singes the fabric twice at one operation. Over the machine is an exhaust fan or ventilator, the pipe from which is furnished with two branches, having longitudinally openings immediately over each pair of rollers, the draught from which strengthens and steadies the flame, and at the same time carries off the down or dust produced by the singeing process. The gas pipes are mounted on cross bars at each end, so arranged as to be capable of being raised or lowered so as to raise or lower the flame as required. The machine is also provided with brushes either fixed or revolving to raise the pile at the moment of singeing. *Patent completed.*

2372. H. Harren. *Improvements in the manufacture of paper, and other productions in which fibrous material is employed.* Dated August 27, 1862.

In carrying out this invention, the inventor uses seaweed or other aquatic vegetable production, cleanses the same in fresh water, and steeps it in naphtha or spirits of wine, or in a mixture of either of them and water, or in chlorine, or in any gas, or liquid, or composition possessing the requisite bleaching properties. When sufficiently prepared he reduces the material into pulp by the usual or best known process. *Patent abandoned.*

2373. J. A. Coffey. *Improvements in the manufacture of salts of ammonia and other products from the ammoniacal liquors of gas works and animal charcoal works.* Dated August 27, 1862.

The apparatus for carrying out this invention is not described apart from the drawings. *Patent completed.*

2374. R. Sims. *Improvements in machinery or apparatus for pulping, stripping, or slicing turnips and other vegetable substances.* Dated August 27, 1862.

This invention relates to improvements in machinery for cutting, stripping, or pulping turnips or other bulbous roots for the use of animals, and consists in the use of a revolving double cone for hand or other power, having teeth or knives formed upon or fixed to its internal or external slant sides, and in the peculiar arrangement of the parts therewith connected. *Patent completed.*

2375. W. H. Turner. *Improvements in machinery or apparatus for carding cotton and other fibrous materials.* Dated August 27, 1862.

This invention is carried out in the following manner:—First, the patentee places under the "licker-in cylinder" of the carding engine a number of grate bars of varied angular shapes. The tops of the bars are formed so that when in their places they appear like the teeth of a circular saw inverted, but having spaces between them which gradually widen towards the bottom. At varied intervals the bars are formed of different angles. The front surface of the first bar is placed at an angle much more acute than if it radiated to the centre of the "licker-in cylinder," in order to give effectual resistance to the dirt and refuse contained in the cotton or other fibrous material, and the front sides of the other bars are placed at such varied angles as to afford a similar or gradually decreasing resistance, by which means the dirt is precipitated below, while the material passes forward in a clean state to the main cylinder. Secondly, he attaches to the frame of the carding engine under the main cylinder two supports or bends for carrying a number of boards or plates capable of being adjusted to any angle and position, and each having a portion of its surface in sufficiently close contact with the cards so that the cylinder may carry forward those fibres of cotton or other material which would otherwise be thrown off as fly or waste. *Patent completed.*

2376. C. Clark. *Improvements in tea and other trays for the table, used in urns and apparatus intended to be used therewith.* Dated August 27, 1862.

This invention consists in making trays for the table with a centre piece in or upon which the iron or apparatus for making and containing the tea, coffee, or other beverage is mounted or fitted, and with a moveable or rotating plate upon which the tea, coffee, and other services are placed, so as to be filled from the urn as they move or revolve therewith. The said plate or tray with its contents can then be moved at pleasure for serving purposes. *Patent abandoned.*

2377. G. Lindsay. *An improved mode of arranging and disposing guns in ships employed in naval warfare and otherwise.* Dated August 27, 1862.

This invention is carried out as follows:—Instead of placing the guns of ships above the water-line of the ship's draught, as commonly practised, the inventor proposes to place and employ them below the water-line, and to use them for attack or destructive purposes as a substitute for the ram now employed. The following are the means by which this invention may be carried into practical effect. He forms a circular hole through the ship's bows, and fits therein loosely a pipe, say six feet long or more, the said pipe having a flange formed thereon for connecting it to the mouth of a gun, either breech-loading or otherwise. The aforesaid pipe is surrounded by a stuffing-box placed inside the ship to enable the pipe to slide water-tight therein. A plug is used at the outer end of the aforesaid pipe to exclude entrance of water thereinto, and a slide valve placed at the inner end of pipe, being let down immediately on the discharge of the gun, excludes the water also from said gun. The gun is mounted on wheels for advancing same forward. In using a gun thus arranged, the pipe is caused to protrude through the ship's bows, so that, when the mouth of the pipe comes into contact with an opposed object, the pipe will be pushed back, and operating on mechanism, will discharge the contents of the gun, thus rendering such discharge of the gun self-acting. *Patent abandoned.*

2378. W. M. Mayes. *An improvement in, or addition to, wheels, particularly applicable to the wheels of railway and other carriages.* Dated August 27, 1862.

This invention consists in inserting in the nave of wheels, or in a box or casing surrounding the axle or nave, a spiral spring or springs. The springs surround the axle and all shock or jar to the axle during the running of the wheels is prevented. *Patent abandoned.*

2379. R. A. Brooman. *Improvements in machinery for separating or sorting and washing coal and other minerals.* (A communication.) Dated August 27, 1862.

The machinery hereafter described may be used for effecting the separation and washing of coal and other minerals, or for effecting one or other of those operations. The machinery for separating and sorting minerals is as first hereafter described. The material is introduced through a hopper, and is delivered on to a revolving horizontal disc, from whence it is forced by a stationary scraper on to a circular classing table, composed of a grating divided into several concentric belts or zones, in each of which the grating is of a different degree of fineness. When rotary motion is imparted to the horizontal disc at the rate of four or five revolutions a minute, the classing table is made to make one revolution per minute. A central shaft passing through the table supports one or several rakes, which stir up the material on the table. When the table has made about three-fourths of a revolution, a fixed stop bars the passage to such portion of the material as may not have passed through the grating in the outermost belt, and projects or guides it on to the next belt nearer the centre, and so on for all the belts. The matter passing through the several gratings falls in sorted masses on to separate annular tables under each belt, and is taken off for use or is received for washing in buckets on an endless belt, which raises it to the washing machine hereafter described. In the machinery last described, the gratings are in the same plane, but a modification of the machine is made by placing gratings of different degrees of fineness under one another. Scrapers remove or scrape from each grating such matters as may not have passed through them. In acting upon coal, the finest particles are subjected, after leaving the tables and before entering the buckets to be washed, to a strong blast, in order to drive off the lightest particles, which otherwise would form a kind of mud in the washing machine. The washing apparatus, which may be combined with or separated from the sorting machine, is constructed as follows:—A large piston made to move up and down is fitted in an open cylinder in a large tank. The piston is surrounded by a flat belt placed horizontally between two upright rings, and free to move upon rollers. The belt is formed of a grating covered with metallic cloth, upon which the materials to be washed are placed. The materials, when the two machines are combined, are delivered by an endless chain carrying buckets into the washing machine. The belt is so inclined that each of the points of its circumference, in the course of its rotation, plunges successively at the same spot in the tank, while each point diametrically opposite is entirely out of the water. The material to be washed is delivered on to the belt, and passed under a rule or guide to regulate the thickness of the layer on the belt. The belt then carries the material under rakes, which stir it up and mix it with the water. The belt takes on the materials under a scraper made to descend a given distance into them. This scraper removes the upper layer, and guides it into a bucket wheel, which delivers the materials out of the machine. Another set of scrapers acts in a similar manner on a deeper layer. When coal is being washed, these two layers comprise the best of the coal of two different degrees of purity. The third and remaining layers are removed by other scrapers and wheels, and any remaining refuse may be taken off by hand. *Patent completed.*

2380. W. E. Newton. *An improved method of producing light for the various purposes of artificial illumination.* (A communication). Dated August 27, 1862.

This patentee claims—1, The use of common or atmospheric air, in the place of oxygen gas, in the combustion of illuminating gas, or its equivalent, for the production of an intense degree of light, when such atmospheric air has been previously heated, and in that state is forced by properly arranged jets into intimate contact with the illuminating gas at or before the moment of combustion, both being at the same time made to impinge upon a suitable piece of lime, or other known equivalent substance, as described. , 2 The use of common atmospheric air in the combustion of illuminating substances, such as illuminating gas, oils, or hydrocarbons, or their equivalents, for the production of an increased degree of light, when such atmosperic air has been previously heated, and in that condition is brought in intimate contact with any of the said illuminating substances, at or before the moment of combustion as set forth. *Patent completed.*

2381. J. G. Nutting. *An improvement in the manufacture of buttons.* Dated August 27, 1862.

This invention relates more particularly to the metal button used for soldiers' clothing, but may also be applied to buttons suitable to ordinary clothing purposes. The invention consists in making the shank loose in the back of the button, instead of soldering it rigidly thereto as usual. By this means the shank may be pushed back into a recess made in the back of the button. The button is made hollow as usual, and the shank when pushed in will not project out from the body of the button, and will not, therefore, be liable to cut the clothing when the latter is tightly compressed, as is usual when required to be packed for transport on shipboard to distant countries. *Patent completed.*

2382. A. F. Newton. *Improved machinery for printing from engraved plates.* (A communication). Dated August 27, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2383. H. W. Cook. *Improved apparatus for obtaining motive power, applicable for driving machinery, or for other purposes where motive power is required.* Dated August 27, 1862.

This invention has for its object the employment of the axial force of electric coils to produce a motive power for driving machinery. *Patent abandoned.*

2384. J. J. Potter. *Improvements in upright pianofortes.* Dated August 27, 1862.

In the action of upright pianofortes it is common to employ a fixed rail placed in front of the fly to check it after it has escaped from the incline of the lever or instrument on which it acts. Now, according to this invention, the patentee employs this rail not only to check the fly, as heretofore, but also both to regulate the distance it enters under the incline of the lever, or instrument, and also to insure its escape up this incline at the proper instant. This he does by forming an incline on the under side of the check rail, and rising from back to front thereof, and he mounts an adjustable button on the fly; this bears on the incline of the check rail, and so regulates, according as the button is set, the distance the end of the fly enters under the incline of the lever or instrument on which it acts. And, further, when the finger-key is depressed, if the end of the fly does not of itself escape up the incline on the lever or instrument at the time it should, it will immediately be drawn off by the incline on the check rail, and thus blocking is effectually prevented. *Patent completed.*

2385. J. Kitchen. *Improvements in ventilators.* Dated Aug. 28, 1862.

This invention is carried into effect as follows:—A ventilator to be applied to (say) a roof of a building, may consist of a vertical cylindrical, or other suitably shaped pipe, the end being formed with an enlarged flanched lip extending downwards, and the lever end being formed with a trumpet mouth, and surrounded with a suitable perforated guard, suspending a hollow disc, having its concave side inwards. This shaft extends below the interior of the roof of the building a given distance, and is surrounded from the roof upwards by an octagonal or other suitably shaped casing, slightly tapering towards the top, and of sufficient capacity to form a chamber or passage between the outer surface of the first described vertical shaft and the inner side of the outer casing, forming a passage for the egress of the foul air which escapes between the upper edge of the outer casing and the curved enlarged flanche or lip of the inner shaft in a downward direction. The shaft and its outer casing is surrounded by a dome or other suitably shaped cap, which in the case of an octagonal outer casing is supported by eight brackets or trusses springing from the angles thereof, and is internally divided by vertical partitions into four equal compartments, and this cap being formed of a greater diameter, and having its lower edge extending downwards to a horizontal line with the lower edge of the turned lip of the vertical shaft (or thereabouts), forms the passage by which the fresh air enters and descends the vertical centre air shaft through the perforated guard into the room. The internal or fresh air shaft is fitted with a throttle valve which can be regulated by a cord carried over pulleys, or by rods and bars, or in any other convenient way. The inventor prefers to weigh the valve so that it will remain open through the cord or other gear. The foul air passage formed between the vertical shaft and the outer casing is also fitted with valves or ports, so that the whole or any portion of the passage may be closed at pleasure by means of a system of cords and pulleys, or in any other convenient way. The lower end of the outer casing immediately below the roof is surrounded by a funnel or trumpet-mouthed lip, and which on the under side is enclosed by wire work, or a suitable perforated plate. The lower edge of the dome or cap may also have lateral perforations formed therein for the admission of air. *Patent abandoned.*

2386. M. A. F. Mennons. *Improvements in smoke-consuming furnaces.* (A communication.) Dated August 28, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2387. M. A. F. Mennons. *An improved assorting apparatus applicable to the "numbering" of raw silks.* (A communication.) Dated August 28, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2388. G. Biddle. *An improvement or improvements in the manufacture of brooms.* Dated August 28, 1852.

In carrying out this invention, the inventor takes a broom head of the ordinary form, that is, of a semi-cylindrical form. He drills a series of longitudinal holes in this broom head in a plane parallel to the flat side, the number of the holes being equal to the number of rows of bristles, tufts, or knots of fibre to be placed in the broom. The said holes are drilled from one end to nearly the other end of the broom head. He also drills holes in the flat side of the broom head, for the reception of the tufts or knots of fibre, the last mentioned holes opening into the before-mentioned longitudinal holes. He takes fibres double the length of the tufts or knots in the finished broom, and he doubles the said fibres at their middle so as to make tufts or knots of the required size. By means of a large needle, a piece of strong string is passed along one of the longitudinal holes, and being drawn out of one of the holes in which the tufts or knots of fibres are inserted, the said string is passed over the doubled part of the tuft or knot, and the said tuft or knot is drawn into the said holes by the tightening of the string. The string is in succession passed over the doubled part of all the tufts or knots to be inserted in one row of holes, and the tufts or knots are drawn and fixed in the row of holes. The string is fixed by being wedged in the hole at the end of the broom head by means of a plug of wood. Tufts or knots of fibre are placed in a similar manner in the holes of each row. *Patent abandoned.*

2389. J. J. Moeckel. *Improvements in machinery or apparatus for spinning cotton, wool, or other fibrous materials.* Dated August 28, 1863.

This invention relates to the self-acting mule, and consists of an improved self-acting regulator, with a differential stretcher for regulating the action of the nut on the screw of the quadrant during the formation of the bottom of the cop. One of the band or chain pulleys connected to the carriage carries on a crank pin a pinion which revolves round and gears into two toothed wheels, one having one tooth more than the other. One of the said wheels is stationary, and the other revolves and gears into a larger toothed wheel working on a stud fixed to the carriage, and gives motion to a plate having in it an eccentric slot, which, as it turns, gives motion to a rod connected to one end of a lever on the counter faller shaft. To the other end of this lever is connected one end of a chain, the other end of which is attached to another lever on the same faller shaft. The chain at the bottom is connected to a brake lever for acting on a brake pulley fixed to a band or chain pulley attached to the carriage, and communicating motion to the screw of the quadrant. When the brake is relieved from the pulley, the latter resumes its rotation round the band, and the nut of the quadrant remains at rest; and the time at which this operation is performed is regulated or determined by the before-mentioned differential wheels and parts connected with them. The brake is suspended during the operation of spinning the other part of the cop by connecting one end of the chain to a lever on the faller shaft. *Patent completed.*

2390. E. Lachenal. *Improvements in gas metres.* (A communication.) Dated August 28, 1832.

We cannot here quote the details of this invention. *Patent completed.*

2391. W. Husband. *Improvements in water valves.* Dated August 28, 1862.

The patentee claims.—1, Casting or forging into one valve, or otherwise connecting two or more domes or rings, each with two or more beats, to close on a seat with four beats, more or less, always adapting the number of beats to the size of the valve or pump; the larger the valve the greater the number of beats that may be used with advantage. 2, Casting the arms which unite the various-inclined from a vertical plane, and in such a way that the valve when rising by the action of the water or falling through the water shall rotate, thus ensuring an equal wear or the beats, guides, and interior of valves. 3, Giving the upper part of the valve the greatest proportional lifting area, whenever there is sufficient height in the valve box, thus keeping the centre of gravity low down, and diminishing the tendency to cant to one side. And, lastly, Making the seating of the valve approximate to the form of a hollow cone, and dropping the valve therein, substantially as described and for the purposes set forth. *Patent completed.*

2392. G. Cooke. *An improved apparatus for securing and fastening doors to prevent robbery or intrusion.* Dated August 28, 1862.

This invention consists of a stick in the form of a walking stick, the upper part or handle being formed with a crescent or crutch-head for the purpose of placing it beneath the handle of a door, the key, or the lock itself. The crescent or crutch-head may be formed of a separate piece, and inserted into a hole bored in the upper end of the stick, and moved upward or downward, according to the height required to place it; and the crutch-head is to be kept up in its place by a metal pin passing through a hole in the upper end of the stick, and through any of the corresponding holes in the stem of the crutch-head. Thus, for travellers, this apparatus may be used as a walking stick, but when required for permanent or continued use as a fastening, the whole may then be made of iron. *Patent abandoned.*

2393. C. Humfrey. *Improvements in the treatment of petroleum to render it non-inflammable.* Dated August 28, 1862.

The object of the processes hereinafter described is perfectly to divest the petroleum of the gas it holds in solation. The inventor takes a closed iron vessel (an ordinary cylindrical steam-boiler with egg ends will answer the purpose), and fills it to about three-fourths of its capacity, or rather more, with petroleum. The steam-chest of this vessel is placed in communication with an air pump, and a vacuum or partial vacuum produced: under this influence the gas dissolved in the petroleum will be liberated freely, and being drawn off by the air pump will be blown away. The vacuum still being maintained, he heats the petroleum by means of a steam jacket, or dry steam worm, to about 120 deg. Fah., when a further quantity of gas will be disengaged and blown away by means of a perforated pipe placed at the extreme bottom of the boiler, and furnished with a stop cock. He then allows a current of atmospheric air to be drawn in minute streams through the petroleum; this, aided by the gentle heat and by the exhaust, will carry off the last portions of the dissolved gas. The petroleum may then be run into the casks from which it was taken, and be stored without danger. *Patent abandoned.*

2394. P. L. Guilband and N. V. Thire. *An improved self-inking hand stamp.* Dated August 29, 1862.

This improved hand stamp is engraved in the usual style on the projecting portion of the surface of a moveable cylinder; the ends of the axis of the said cylinder run in arms or levers hinged at the lower ends of a T-shaped frame, carried by a suitable handle; an inking-roller runs on the same levers, touching as it revolves the engraved portion of the cylindrical stamp. A pinion fitted on the said stamp is actuated by a segmental rack, which rack is carried by angular levers V hinged also on the ⊥-frame. The angular levers carry a segmental portion of a cylindrical frame, which, being applied upon the paper to be stamped and borne upon, caused, by pushing forward the rotary motion of the cylindrical stamp, the projecting engraved portion thereof to imprint its marks upon the paper, which the lower plain portion cannot touch, whilst the cylindrical segmental frame maintains the paper firm and even. Now when the stamp is lifted up, a spiral spring wound round the axis either of the stamp or of an intermediate pinion, by its unbending action, brings back the engraved cylinder to its primary position, in which motion the engraved portion is inked by the inking-roller. *Patent abandoned.*

2395. H. Jones. *Improvements in breech-loading firearms.* Dated August 29, 1862.

This invention relates to such breech-loading firearms as are opened at the breech for charging by the barrel or barrels turning upon a joint, the muzzle end of the barrels being depressed, and the breech end elevated and separated from the face of the body. In making breech-loading firearms of the kind described, the patentee effects the locking and unlocking of the barrels by means of a slight sliding motion. A bolt below the breech of the barrels is made by the said sliding motion to engage in a hole or recess in the face of the body, and a bar formed in the body at the same time engages in a horizontal slot in the lump on the under side of the barrels. The barrels are thus fixed in a horizontal position at two points during discharge. This bolting of the barrels is effected when they are made to slide horizontally towards the face of the body, and when they are made to slide in a contrary direction they are unbolted and can be turned upon their joint. The sliding motion of the barrels and the holding of the breech ends firmly to their bearing against the face of the body during the discharge of the gun, is effected by means of a lever on the under side of the body, the said lever having motion in a vertical plane. When the said lever lies horizontally on the under side of the gun, it holds the breech end of the barrels against the face of the body, and as the said lever is depressed into a vertical position, it liberates and gives them sufficient sliding motion to unbolt them and permit them to turn upon their joint. *Patent completed.*

2396. F. H. Lefranc. *Improvements in the manufacture of casks.* Dated August 29, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2397. W. Smith. *Improvements in the construction of furnaces.* (A communication.) Dated August 29, 1862.

This invention relates to furnaces for generating steam, and for other purposes, and is intended for burning fuel smokelessly and economically. The furnace bars are hollow, and arranged so as to form an inclined grate rising from the front upwards to the back; the bars are connected at their superior and inferior extremities to hollow transverse bearing bars, forming a tubular system through which the feed water is made to circulate rapidly, and is thereby heated before entering the boiler. The feed water enters the tubular arrangement at the lower transverse hollow bearing bar, and having circulated through the tubular grate, the supply of feed water thus heated is taken from the upper hollow bearing bar. By the disposition of the grate at a considerable angle upwards from the front to the back, the products of combustion arising from the distillation of the green fuel are, by the admission of the air in front and above the bars, made to pass downwards through the burning fuel and between the bars, and the gases and carbonaceous matters generated are consumed by the incandescent substratum of fuel, and the production of smoke thereby prevented, and thus the greatest amount of heat due to the combustion of the fuel is generated and utilized. *Patent abandoned.*

2298. J. Davis. *Improvements in the manufacture of spoons, forks, and similar articles.* (A communication.) Dated August 29, 1862.

This invention relates to the manufacture of spoons, forks, and similar articles when the same are stamped out of single pieces of sheet metal, and consists in giving the handles thereof a central corrugation, and a bead around such corrugation, for the purpose of imparting strength to the narrow and weak part of the handles, whilst at the same time the hand obtains a better grasp, and the appearance of the article is improved. In the manufacture of spoons, the aforesaid corrugation and bead are to be carried into the bowls thereof. The corrugation and bead are formed by suitable dies when the articles are being constructed by the processes well known in the manufacture of such articles. *Patent completed.*

2399. H. Harben. *Improvements in the manufacture of cotton, cotton fibre, and other similar fibrous productions.* Dated August 29, 1862.

In carrying out this invention, the inventor uses sea-weed or other aquatic vegetable production, either whole or in pieces, and steeps it in fresh water for the requisite period, for the purpose of extracting any salt and otherwise cleansing it. He then separates the fibre from the waste, either by hand labour or by the most approved method now in use for similar purposes, or by machinery and hand labour combined; or, instead of fresh water, as above, he cleanses and looses the fibres by steeping the plant or weed in a solution of American potash, or other suitable liquid composition or gas. The work for loosening the fibres may also be performed by crushing or scarifying the peant or weed by machinery, or by subjecting it to steam. *Patent abandoned.*

2400. George Dyson. *Improvements in machinery for finishing and polishing circular metal rods, bars, and shafts: applicable also to the manufacture of metal tubes and pipes.* Dated August 29, 1862.

This machinery consists of a pair of rolls, set slightly at an incline, and each inclined in an opposite direction to the other, both rolls being driven in the same direction. The rod, bar, or shaft is introduced between guides and between the ends of the rolls, and at right angles or nearly so to the direction in which the rolls are driven; then upon the rolls being made to rotate through toothed gear, the rod, bar, or shaft is drawn between the rolls in a direction at right angles or nearly so to the circumference thereof, and is thereby rendered cylindrical, smooth, and polished. *Patent completed.*

2401. W. Owen. *Improvements in the manufacture of railway wheels and tyres, and in securing tyres to wheels.* Dated August 29, 1862.

This invention is not fully described apart from the drawings. *Patent completed.*

2402. P. W. Mackenzie and S. W. Smith. *Improvements in vehicles to be propelled by the rider.* Dated August 29, 1862.

The first part of this invention relates to the construction and combination of parts by means of which the propulsion of the vehicle is accomplished. In this device a double-cranked axle is used, and in the arrangement which the patentees have adopted as the best, two cranks are formed in the same parallel line to the centre, and one upon the side opposite, and at the same time or nearly the same distance from the centre of rotation. The seat of the rider is connected to the two cranks which are on one and the same line, and the pedal upon which the feet press are connected to the other crank for the purpose of giving continous rotation, and, consequently, locomotion by means of the transfer of the weight of the body alternately from the seat to the pedal and *vice versa*. The second part of this invention relates to the mechanism hanging and supporting the steering wheel, it being supported in segmental bearings. The segmental bearings in which it is hung, are allowed to turn in a circular plate made in two parts, and attached to the parts which extend down astride of the said steering wheel. The third part of the invention relates to the manner of connecting and arranging the steering gear in relation to other parts. A forked lever is attached either to the segmental bearings or to the axle of the steering wheel, which, by means of a further lever and other connections, is operated by a cross bar or bit with reins attached the same as an ordinary bridle. The seat of the rider the patentees usually prefer to make in the form of a horse, and the bit is then placed in the mouth of the figure of the animal. The fourth part of this invention relates to the construction of the seat of the rider in such a manner as to give an erect position to the rider, and so mounting the said seat on wheels as to facilitate the operation of propelling the vehicle by giving the body and lower limbs a position and opportunity to change their position in a manner suitable to effect that purpose, the construction and arrangement of parts being such that the vehicle can be guided in any direction. The fifth part of the invention relates to making the body of the figure of the horse or other seat hollow, and the disposition of the steering gear in relation thereto, so as to make the seat as light as possible, and cover and protect the gear. *Patent completed.*

2403. R. Courtenay. *Improvements in obtaining motive power.* Dated August 29, 1862.

This invention consists in producing motion by changing (increasing or diminishing) the specific gravity of an elastic fluid, the change being effected by revolving weights. *Patent abandoned.*

2404. W. Upfill, W. Morton, and W. Asbury. *Improvements in the construction of wheels and axletrees for carriages.* Dated August 29, 1862.

This invention relates to a novel mode of constructing and combining the naves and axle-boxes of wheels, and also to a novel mode of securing the nave or axle-box of the wheel to the axletree. In carrying out this invention the nave and axle-box are constructed separately; but previously to being adapted to the axletree they are secured together by screwing or otherwise. The nave which receives the spokes of the wheel is bored out or cast with a hole to fit on to the axle-box, on which it is secured by a screwed cap, or by bolts, or otherwise. By this means the nave, with its cap and axle-box are all connected together and form one piece, which is secured on to the axletree by means of tongues, pins, studs, or projecting pieces, which are made to take into a groove or grooves cut or made round the axletree. These tongues, pins, studs, or projecting pieces are made moveable, and are inserted in dovetailed grooves or sockets made in the metal washer, which is by preference cast on to the end of the axle-box, but may, if desired, be made separate; and in order to prevent these tongues, or their equivalents, from coming out accidentally, they are secured in their places by cross pins or screws. *Patent completed.*

2405. E. A. Pontifex. *Improvements in the manufacture of steam traps.* Dated August 29, 1862.

This invention is carried into effect as follows:—The steam and water are allowed to enter a reciprocating rocking or moveable vessel or chamber, which is properly balanced, and is provided with valves or openings which are opened and closed as the vessel rises and falls. When the balanced vessel has received a given weight of water from the condensation of the steam, it will be carried down by its weight, and in so doing will uncover or open a valve at the bottom of the vessel, and allow the water to run out. The vessel thereby lightened will then be raised up again by the counterbalance weights to its original position, and will close the exit openings or valves until more water or condensed steam accumulates in the vessel, when the latter will descend again, and will allow the water to run out *Patent completed.*

2406. E. T. Hughes. *Improvements in the manufacture of woven fabrics.* (A communication.) Dated August 30, 1862.

This invention consists in using straw instead of the usual materials for the weft with any strong material, such as flax or hemp, for the warp-threads; cotton or wool may be used, but it will not be so durable as flax. The inventor uses an ordinary loom, such as is generally used for weaving linen cloth; but to facilitate the use of the straw, he makes the shuttle with a spring from the centre extending to each end, the ends of which spring being pressed down allows the straw to enter the openings. To keep up the supply of the straw weft, he places an assistant at each side of the loom (a child will be sufficient), and supplies each of them with one or more extra shuttles, so that they will always be ready with a charged shuttle to place on the loom as it is required. This fabric may be advantageously used for carpets, floor-cloths, window-blinds, and similar purposes. *Patent completed.*

2407. E. C. Harding and C. Doody. *Improvements in braces.* Dated August 30, 1882.

Instead of the ordinary method of buttoning the braces to the back and front of the trousers, the patentees fasten them to the sides, and dispense with the back buttons altogether. They form each of the main bands of the brace of two parts placed in an angular position with each other, and attach the two main bands so formed by a cross-piece at the back, at or about the shoulders, and bring one end of each band to the side and attach it to the trousers or to straps buttoned to them; the other end of each band is brought over the corresponding shoulder and attached to the band near the trousers, or directly to the side of the trousers, either of which arrangements will prevent the trousers dragging or tearing when the the wearer is in the act of stooping, or in a sitting posture, as well as securing many other advantages. *Patent completed.*

2408. F. Le Conte. *Improvements in the construction of furnaces for steam boilers used in sugar mills, distilleries, breweries, &c.* Dated August 30, 1862.

This invention consists, essentially, in the production of whirlwinds of air by means of the bars of the focus of a fireplace, the air escaping through openings made in the bars in contrary directions. This effect is obtained by giving passage to straight or direct currents of air, and to other currents of air directed perpendicularly or obliquely upon those first-mentioned, and the form of the bars may vary, so that this main condition be preserved. *Patent completed.*

2409. W. E. Gedge. *Improvements in machinery or apparatus for manufacturing velvet.* (A communication.) Dated August 30, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2410. J. H. Johnson. *Improvements in coating or covering metallic surfaces with copper.* (A communication). Dated August 30, 1862.

This invention relates to the coating or covering of wrought or cast iron, zinc, or other metallic surfaces with copper, by means of the magneto-electric or electro-galvanic processes, and consists in the employment of certain peculiar compositions, which are applied by means of a brush or other suitable method to the metallic surfaces to be coated with copper, before placing them in the cupreous bath for the purpose of forming an intermediate coating between the copper to be deposited and the metallic surface to be covered or coated, thereby avoiding the deleterious action which arises frequently when the copper is in immediate contact with the metal upon which it is deposited. *Patent completed.*

2411. J. Meyer. *Improvements in mechanism for the production of Jacquard cards, and in the said cards or card-boards.* Dated August 30, 1832.

This invention is not described apart from the drawings. *Patent completed.*

2412. G. N. Alleyne and J. Roberts. *Improvements in the manufacture of flanged wrought-iron or steel plates, or of wrought-iron beams and frames of a trough-shaped section.* Dated September 1, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2413. J. Nickson and T. Waddingham, jun. *Foundation or groundwork for plaster for ceilings, walls, partitions, &c.* Dated September 1, 1862.

This invention consists in the use of plates or slabs of slate, metal, earthernware, or other similar and suitable material perforated with round, square, or other shaped holes, or with oblong slots for the purpose of retaining the plaster, a space being left between the adjoining edges of the plates when placed in position for the same purpose. The said plates are nailed or otherwise attached to the joists, spars, or battens, and are made of a suitable size to cover the spaces between the same; or they are attached to studs projecting at suitable intervals from the surface of the wall to be covered, so as to leave a space between the wall and the plastering, which is more particularly adapted to the outer walls of buildings, or to walls exposed to damp. *Patent completed.*

2414. J. Walker. *Improvements in the treatment of kelp.* Dated September 1, 1862.

The patentee claims the preparing of hydrosulphite of soda, borax, iodide of sodium, iodide of potassium, and iodine from or by means of kelp liquors or products, as described. *Patent completed.*

2415. W. E. Gedge. *Apparatus for washing the felts of paper-making machines.* (A communication.) Dated September 1, 1862.

This apparatus is composed of a wooden or cast-iron receiver or reservoir, fed by a current constantly renewing and keeping the water in the reservoir at the same level. This apparatus is placed beneath the felt coucher, which is brought to it by rollers when retained empty or uncharged. In the apparatus and beneath the water are two parallel rollers, working the one towards the other, and exercising on the felt, which passes between them, a pressure which purges it from the foreign and earthy matters with which it may be charged. On leaving this bath, the felt passes through two other rollers covered with felt or caoutchouc, the pressure of which frees it of the excess of water, and clears off any remaining extraneous matters, so that thus disembarrassed it presents itself anew beneath the press and the wet paper carrier in a thoroughly clean state, and as the felt is thus washed at each revolution, it may be worn out on the machine without ever having been removed for washing. *Patent abandoned.*

2416. J. Ellis. *Improvements in corsets.* Dated September 1, 1862.

This invention consists in combining a great number of narrow pieces of linen or other coutille, or other suitable material, each piece being cut or shaped according to the figure and the size of the article required. Although the patentee prefers to make corsets according to this invention from fifty separate pieces of material, any greater or lesser number may be employed. He joins several narrow pieces of material together side by side, by overlapping to such an extent as when two single or double rows of sewing or stitching have been made, a space will be left along the sewn joints forming a groove or channel, into which a piece of whalebone or other suitable material is inserted, and such pieces of material may be plain or covered. *Patent completed.*

2417. J. W. Newton. *Improvements in apparatus for preparing, spinning, and doubling cotton, wool, &c.* Dated September 1, 1862.

This invention consists—First, in an improved method of effecting the twisting or winding on of the yarn or preparings, either in the form of cops or bobbins, by means of a ring, instead of the ordinary flyer, which ring is used in the several operations of preparing, spinning, doubling and twining, and is applicable to all machines where flyers are used in the manufacture of yarns or threads of cotton, or other fibrous substances. Secondly, in improved methods of obtaining the drag when spinning and doubling. The details are voluminous. *Patent aompleted.*

2418. E. G. Fitton. *Improvements in machinery for winding yarn and thread on to bobbins or spools.* Dated September 1, 1862.

This invention consists—First, in a novel combination and arrangement of mechanism, whereby the mechanical movement or action, which in the ordinary machine drives the single spindle and regulates the winding on and pressing down of the thread on a single spool or bobbin, is applied simultaneously to two or more spindles, and the spools or bobbins thereon in the same machine, by which means the operative is enabled to attend simultaneously to as many spools or bobbins as there are spindles in the machine, instead of to one only. Secondly, in the application and adaptation of toothed gearing to hand spooling machines for connecting two or more spindles when several are employed in the same machine, in order to secure greater regularity in winding than when such spindles are driven by bands or cords. Thirdly, in the application of a spring made of india rubber, or any suitable compound thereof, to each guide or presser used for guiding and pressing down the yarn or thread, whereby the necessity of pressing the guide by hand is obviated. Fourthly, in a novel arrangement of mechanism, whereby the several guides or pressers used for guiding and pressing the yarns or threads on the several bobbins in the same machine can be simultaneously operated upon, and which the patentee effects by the following means:—A cord or chain attached to a lever passes partially round antifriction bowls or pulleys placed upon the fixings on which the guides or pressers are supported, so that by pressing down the lever, either by springs, weights, or the hand of the attendant, a suitable degree of pressure is given to as many pressers as may be arranged in one machine. Fifthly, in an arrangement of mechanism, wherein a series of pins on one or more vertical bar or bars raised and lowered by levers or other convenient means act simultaneously on the guides or pressers, so as to lift and hold them up or allow them to be depressed as required. Sixthly, in the application and arrangement of mechanism wherein a lever brought into action by the hand or foot of the attendant moves one or more sliding bars or levers to which a doffer plate is attached, so as to push or liberate the bobbins from the spindles. Seventhly, in an arrangement of parts applied to such machine as aforesaid to polish or size at the same time the yarn or thread on as many bobbins or spools as there are spindles in the machine, by the means of a socket or slide attached to the traversing bar, or to each of the presser fixings, or to other convenient part or parts of the machine, in or on which socket or slide a piece of wood or other substance is placed covered with a suitable material for polishing. *Patent completed.*

2419. J. Watt and T. S. Haviside. *Improvements in the treating of flax and other similar vegetable fibrous substances to be used as substisutes for cotton.* Dated September 1, 1862.

This invention consists in subjecting the flax or other similar fibrous substance to the action of proto-carbonate of soda, or bi-carbonate of soda, or proto-carbonate of potassa, or bi-carbonate of pottassa, or soda ash, in solution in water, and heating the whole to the boiling point, and boiling the same until the fibrous substance has been so acted upon that, upon being washed and treated with an aqueous solution of chloride of lime or chloride of soda, it is converted into a substance which may be applied as a substitute for cotton. *Patent completed.*

2420. W. Edge. *Improvements in Albert chains.* Dated September 1, 1862.

This invention consists in constructing Albert chains as follows:—The inventor makes a ring at or near the middle of the chain, which is so arranged that the ends of the chains can easily be released, being constructed with a small hinged portion which is kept in its place by a spring to make a break in the ring, so as to insert the ends of the chain; this hinged portion is pressed inwards with the finger. The ring also supports the chain, locket, and other ornaments. To fix it to the vest, the chain is passed through the button hole, and the end put on the break ring. An ordinary hook or fastening may also be used, but it is not necessary for the safety of the chain. *Patent abandoned.*

This invention consists in means for producing the combustion of light hydrocarbons, light coal or petroleum oils, and generally of all easily vaporizable liquids, in order to obtain light and heat, and also for the production of mechanical power from the gas thus obtained. *Patent completed.*

2422. J. H. Johnson. *Improvements in the manufacture of braid.* (A communication.) Dated September 1, 1862.

This invention relates—1, to an improved manufacture of flat braid, and consists in making such braid with the borders or selvages thinner than the body or centre portion thereof. According to one mode of producing a braid having this peculiarity, it is proposed to construct a machine somewhat similar to an ordinary flat braid machine, but provided with separate bobbins working in grooves of their own for forming the borders or selvages, and so actuated as to lock their threads with the threads of the other bobbins forming the body of the braid. In order that the borders may be considerably thinner than the body, it is proposed to have fewer thicknesses of thread on the bobbins forming the borders—for example, if each of the bobbins forming the body of the braid have three threads, the outer bobbins will only be supplied with one thread, thus forming the border one-third the thickness only of the body of the braid, which has never heretofore been accomplished. It is, of course, requisite that the speed of the bobbins making the borders should be greater than that of the bobbins making the body of the braid in proportion to the difference in the number of threads carried by each set of bobbins, so that the borders, although made of one thread, for example, will be produced as fast as and keep pace with the body of the braid made from two or more thicknesses of thread. The above-mentioned arrangement affords facility for making braid of two or more different colours—that is to say, on longitudinal stripes. The second part of this invention relates to certain peculiar constructions and combinations of parts of braiding machines, whereby their productive powers are greatly increased, whilst the work executed is superior to that produced in ordinary braiding machines. *Patent abandoned.*

2423. J. H. Johnson. *Improvements in apparatus for regulating or controlling the working of motive-power engines.* (A communication.) Dated September 1, 1862.

This invention relates to an improved mode of regulating or controlling the working of steam, air, or gas engines, or hydraulic prime movers, and consists in causing the steam or other medium employed for working the engine, to act upon the regulating apparatus in its passage from the generator or source of supply to the cylinder or other acting agent as the case may be. *Patent completed.*

2424. D. B. Peebles. *Improvements in wet gas meters.* Dated September 2, 1862.

This invention comprises improvements in various parts of wet gas meters, and which may be used together or separately. A first improvement relates to the valve in the inlet chamber used to shut off the gas when the water in the meter is too low. By the present invention, the float which keeps this valve open is placed in a compartment open at its upper part to the drum case, and separated from the front case by a partition dipping down below the water. A bent wire passing under the partition connects the float and valve. The result of this arrangement is, that a sudden increase of pressure in the service pipe will not close the valve (as frequently happens in ordinary meters), its tendency to do so being counteracted by the opposite tendency of the float, since the pressure in the front case will depress the water therein, and thereby elevate it in the float compartment, and the float with it. A second improvement is designed to prevent a sudden increase of pressure from throwing water up into the compartment containing the counting mechanism. Besides the tube usually surrounnding the vertical counter-spindle, and dipping down below the water surface to seal the communication, there is a second tube which may either encircle the first or be beside it. These tubes communicate with a small chamber near the top of the case, and within this chamber the spindle has fast on it a disc, and any water thrown up one tube strikes this disc, and being deflected thereby runs back by the other tube. A third improvement relates to contrivances in connection with a closed fountain chamber for compensating for the lowering of the water-level in the meter from evaporation or otherwise. *Patent abandoned.*

2425. J. Mosheimer. *Improvements in machinery for amalgamating gold and silver, or the ores thereof.* Dated September 2, 1862.

This invention relates to the machinery employed in the separation of gold and silver from their ores by the agency of mercury, and consists, first, in the use of metal mullers revolving in a circular pan or annular trough, the bottom of which is flat or nearly so, and upon which the materials to be triturated and amalgamated are spread. A second part of the invention consists in admitting steam to a space underneath the bottom of the pan for the purpose of facilitating the amalgamation of the metals. *Patent completed.*

2426. W. Hunt. *Improvement in the manufacture of muriate of ammonia.* Dated September 2, 1862.

The patentee claims manufacturing muriate of ammonia by passing a mixture of volatilized muriatic acid and atmospheric air, or uncombined nitrogen, through burning coke or coal, or other carbonaceous fuel; or passing a mixture of atmospheric air, or uncombined nitrogen, through ignited fuel, with which fuel has been mixed chloride of manganese, chloride of iron, or other chloride capable of yielding chlorine or muriatic acid when heated. *Patent completed.*

PROVISIONAL PROTECTIONS.

Dated Feb. 11, 1863.

378. H. Wycherley, carriage builder, Oldbury, Worcester. Certain improvements in the construction of and mode of applying wings or dirt screens over the wheels of carriages.

Dated Feb. 13, 1863.

386. S. M. Innes, Hill House Hill, Millbrook, Hampshire. Improvements in the construction of pianofortes.

Dated Feb. 14, 1863.

397. G. Haseltine, 12, Southampton-buildings, Chancery-lane. Improvements in lever horse-power machines, the cog-gearing employed being applicable to other machines. (A communication.)

399. J. C. Jeffcott, Anglesey-street, Cork. Improvements in the production and generation of gases, and also in apparatus connected therewith.

Dated Feb. 19, 1863.

453. W. Sherwood, Birmingham, silversmith. An improvement or improvements in wine glasses.

455. R. Pinkney, 18, Bread-street-hill, London, wholesale stationer. Improvements in the manufacture of metallic pens.

457. W. Trustrum, 2, Marlborough-road, Old Kent-road. Improvements in the manufacture of oiled silk.

Dated Feb. 20, 1863.

459. H. B. Barlow, Manchester, patent agent. Certain improvements in weaving, and in the machinery employed therein. (A communication.)

461. W. Marsden, 49, Old Bailey. Improvements in buttons and other similar fastenings, and in the modes of attaching or securing the same.

463. J. Bentley, manufacturer, and H. Booth, overlooker, Pilkington, Lancashire. Improvements in looms for weaving.

465. W. Hainsworth, Rothwell, near Wakefield, York, founder. Improvements in the manufacture of cast-iron pipes, columns, or any description of tubing.

467. W. Clark, 53, Chancery-lane, patent agent. An improvement in boilers for disintegrating and pulping vegetable substances. (A communication.)

469. F. W. Benndorf, Chemnitz, Saxony. Improvements in governors or apparatus for regulating the speed of steam engines, or other engines for driving machinery.

Dated Feb. 21, 1863.

471. C. Malpas, Soho Mills, Tunstall, Stafford. Improvements in ovens or kilns for firing, burning, or baking pottery, bricks, tiles, and other earthen or ceramic articles.

473. H. Kilshaw, Haslingden, Lancaster, cotton spinner and manufacturer, and T. Elce, jun., Manchester, machine maker. Certain improvements in machinery for preparing and doubling cotton and other fibrous substances.

475. E. T. Hughes, patent agent, 123, Chancery-lane. Improvements in the treatment of colouring matters derived from tar for the purpose of making them applicable for painting. (A communication.)

477. A. H. Rémond, 4, Moorgate-street, London. Improvements in preserving provisions, and in the apparatus employed for such purpose.

479. W. Wood, Monkhill, near Pontefract, York. Improvements in the process of manufacturing pomfret or liquorice cakes, rolls, sticks, and pipes, and other similar articles of confectionery.

481. J. Brown, Atlas Steel and Iron Works, Sheffield. York. Improvements in the manufacture of armour plates for ships and other structures. (A communication.)

483. W. E. Newton, 66, Chancery-lane, civil engineer. Improvements in the construction of wind instruments of music. (A communication.)

Dated Feb. 23, 1863.

485. W. H. Gauntlett, South Bank Iron Works, Middlesbro'-on-Tees, York. Improvements in apparatus for heating the blast in the manufacture of iron.

487. J. Eckersley, Westhoughton, Lancaster, mechanic. Improvements in spinning and doubling silk.

489. J. P. F. Datichy, Margaret-street, engineer. Improvements in steam engines.

491. R. Martindale, Birmingham, manufacturer. Improvements in lamps and burners, and in apparatus employed for milling or ornamenting parts of lamps, which apparatus may also be applied to other similar uses.

493. T. and A. L. Dickens, and H. Heywood, Middleton, Lancaster, dyers and printers. Improvements in ornamenting plush and other such textile fabrics.

495. J. Erwood, 91, Goswell-street, paper stainer. Improvements in producing imitation gilding on paper hangings and other surfaces, also in metal leaf and metallic or bronze powder suitable for the purpose.

Dated Feb. 24, 1863.

497. D. Spink, Esq., Spaxton, near Bridgewater, Somerset. Improvements in the construction and arrangement of armour plates for ships.

498. W. and H. Whitehead and H. Barber, spring knife

cutlers, Ecclesall Bierlow, Sheffield, York. Improvements in the manufacture and securing of cutlery handles, and machinery employed therein.

501. G. Davies, 1, Serle-street, Lincoln's-inn, patent agent. An improvement in melting and smelting furnaces. (A communication.)

505. W. Hooper, London India-rubber Works, Mitcham, Surrey. Improvements in insulating and protecting telegraphic and other wires and rods, and in machinery connected therewith.

507. E. R. Walker, Haigh, near Wigan, Lancaster, engineer. Improvements in valves, and in apparatus connected therewith.

509. G. A. Huddart, Brynkir, Carnarvon, gentleman. Improved means of imparting heat to fluids.

511. T. Mallinson, machine maker, Globe Works, Manchester, and J. Livingston, mechanic. Improvements in throstle spinning and doubling frames, wholly or partly applicable to roving and slubbing frames.

513. G. Bower, St. Neots, Huntingdon, gas engineer, and W. Hollinshead, engineer. Improvements in apparatus for the production and transmission of gas or other fluids.

515. W. H. Lapthorn, Broad-street, Portsmouth, ship chandler. Improvements in reefing and furling ships' square sails.

Dated Feb. 25, 1863.

517. F. A. Gatty, Accrington, Lancaster, manufacturing chemist. Improvements in printing and dyeing cotton and other fabrics.

518. R. Maynard, Whittlesford, Cambridge. Improvements in portable chaff-cutting machines.

519. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in lamps for burning petroleum and other similar oils, and in feeders or cans for supplying such oils to lamps. (A communication.)

521. W. Readman, Glasgow, manufacturing chemist. Improvements in the manufacture of carbonate of magnesia, and of iodine and kelp salt, and other products from kelp.

523. J. B. Green, Hayle Mill, Maidstone, Kent, paper manufacturer. Improvements in the manufacture of paper.

525. J. Gailey, Princes-street, Chelsea, joiner. Improvements in apparatus for the purpose of supplying air for mixture with gases and other aeriform fluids.

527. H. H. Henson, 13, Parliament-street, Westminster, engineer. Improvements in mats.

529. W. E. Newton, 66, Chancery-lane, civil engineer. Improvements in producing stereotype plates for printing purposes. (A communication.)

531. N. Thompson, Abbey-gardens, St. John's-wood. Improvements in machinery for sawing wood.

533. A. Macivor, Edinburgh University, chemist. Improvements in veneering or overlaying woods according to two methods—1st, by means of steam exhaustion or steam pressure, or air exhaustion or air pressure; 2nd, by the employment of electro-magnetism.

Dated Feb. 26, 1863.

537. C. Ritchie, engineer, South-street, Finsbury-market. An improved machine for making spiral lighters or spills from wood or other substance, and which machine will make and colour them when desired at one process or operation.

539. W. A. Wilson, engineer, and J. Smith, baker, Liverpool. Improvements in furnace fire-grates.

541. A. P. Price, 47, Lincoln's-inn-fields, gentleman. Improvements in the production and manufacture of blue colours. (A communication.)

543. P. Spence, Newton Heath, Manchester, manufacturing chemist. Improvements in the manufacture of potash, alum, and other salts of potash.

545. M. Puddefoot, Blisset-street, Greenwich, hat manufacturer. Improvements in implements for tilling and cultivating land.

547. R. J. Nodder, Liverpool, hat manufacturer. Improvements applicable to hats, caps, helmets, military head dresses, and other like coverings for the head.

Dated Feb. 27, 1863.

549. J. H. Albinson and H. H. Cocker, Bolton, Lancaster, silk spinners, doublers, and throwsters. Improvements in spinning, doubling, throwing, and reeling silk, and in the machinery employed therein.

552. E. T. Hughes, patent agent, 123, Chancery lane. Improvements in machinery or apparatus for doubling or twisting yarn, thread, braid, rope, or similar articles. (A communication.)

553. J. Carver, Butcher-street Works, Nottingham, bobbin and carriage manufacturer. Improvements in the arrangement or fixing of combs in machines employed in the manufacture of bobbin net or twist lace.

555. J. Fry, Chesham, Buckingham, engineer. Improvements in mashing machinery used in making fermented liquors.

558. W. Gray, Sheffield, machine knife manufacturer. Improvements in the manufacture of beaters for thrashing machines.

559. W. Clark, 53, Chancery-lane, patent agent. Improvements in pumping and forcing water, and in apparatus for the same. (A communication.)

561. J. H. Johnson, 47, Lincoln's-inn-fields, gentleman. Improvements in machinery or apparatus employed in the preparation or treatment of hemp or other textile materials. (A communication.)

Dated Feb. 28, 1863.

562. B. West, 2, St. James'-walk, Clerkenwell, bookbinder. An improvement or improvements in metallic pens.

563. G. Royle, 32, King's-street, Cheapside. A new or improved apparatus for creasing or marking rouches.

564. W. Hadfield, Bolton, Lancaster, boiler maker. Improvements in steam boilers and in the arrangement of flues in connection therewith.

565. J. W. Friend, Freemantle, Southampton. An improved gas meter.

567. J. Maxfield, Warrington, Lancaster, brewer. Certain improvements in brewing and in apparatus employed therein.

568. S. Williamson, Sheffield, engineer. Improvements in the construction of furnaces.

569. D. Collinge, Oldham, Lancaster, cotton spinner and manufacturer. Improvements in machinery or apparatus for cleaning, steaming, and preparing cotton or other fibrous materials to be spun.

570. E. Paine, Liverpool, master mariner. Improved apparatus for facilitating the cleaning of vessels' bottoms while afloat.

571. T. E. Symonds, Adam-street, Adelphi, Commander in Her Majesty's Navy. Improvements in the construction of screw-propelled ships, and in the arrangement and mode of disconnecting, withdrawing, and lifting screw propellers.

572. J. Penn, Greenwich. Improvements in escape or relief valves to the cylinders of marine and other steam engines.

573. J. Courtonay, 9, Down-street, Piccadilly. Improvements in obtaining motive power. (A communication.)

574. E. Hayes, Stony Stratford, Bucks. Improvements in supplying water to surface condensers of marine engines.

575. S. Bateman, Low Moor, near Bradford, York. Improvements in the manufacture of wire rope and cordage, and in the machinery employed therein.

576. G. Haseltine, 12, Southampton-buildings, Chancery-lane. Improvements in sewing machines. (A communication.)

Dated March 2, 1863.

577. O. Murrell, Bethnal-green-road. Improved arrangements for generating steam in steam boilers and other vessels, and for heating the liquid contents thereof.

578. F. Tolhausen, 17, Faubourg Montmartre, Paris, patent agent. Improvements in cloth blankets and other fabrics to be used in machinery for printing fabrics, paper hangings, and letter press. (A communication.)

579. J. W. Burton, Leeds, gentleman. An improved mode of refining and purifying oils.

581. G. Hawksley, Sheffield, manufacturer, and T. Bissell, 75, Tooley-street, London, gun maker. Improvements in powder chargers.

582. E. Habel, Manchester, machinist, and E. Suckow, machinist. Certain improvements in machinery or apparatus for preparing, spinning, and doubling cotton and other fibrous substances.

583. T. Taylor, 7, Wellington-row, Bethnal-green. Manufacture of a new or improved fabric, and its application to the formation of ornaments for fire-stoves and other decorative purposes.

584. C. Garton, Bristol, brewer. An improved method of applying heat in the manufacture and refining of sugar, and in malting, hop drying, brewing, distilling, and vinegar making.

585. J. S. Wells, Mount-street, Nottingham. Improvements in the manufacture of stockings and other looped fabrics made in knitting machines.

Dated March 3, 1863.

587. T. E. Symonds, Adam-street, Adelphi, Commander in Her Majesty's Navy. Improvements in the apparatus for steering ships.

588. T. Emmott, Vale Mills, Oldham, Lancaster, cotton spinner and manufacturer. Certain improvements in mules for spinning and doubling.

589. R. Saunders, Croydon, Surrey. Improvements in metal sheathing for ships and vessels, and in the securing of such sheathing thereto.

590. G. F. Lyster, Liverpool, engineer. Improvements in mooring buoys.

591. R. H. Jones and J. Abrahall, Birmingham, jewellers. Improvements in bracelets and brooches.

592. G. Davies, 1, Serle-street, Lincoln's-inn, patent agent. Improvements in polishing or giving a lustre to soap, and in the apparatus employed in such process. (A communication.)

593. J. Henderson, Bradford, York, carpet manufacturer. Improvements in machinery or apparatus for the manufacture of carpets and other piled fabrics.

595. J. Sibert, Nottingham, machinist. Improvements in apparatus for winding and measuring lace.

596. G. Lamb, 9, America-square, Minories. Improvements in apparatus for recording the revolutions of the propelling shaft of a steam ship or vessel.

597. T. Erich, 77, Newgate-street. Improvements in machinery for pressing peat. (A communication.)

598. D. B. Parsons, 77, Upper Thames-street. Improvements in reaping and mowing machines. (Partly a communication.)

599. B. S. Cohen, 9, Magdalen-row, Great Prescott-street, Goodman's-fields, pencil manufacturer. Improvements in apparatus for protecting the points of pencils.

600. W. Parsons, Earl-street, Edgeware-road, engineer. Improvements in dining tables.

Dated March 4, 1863.

602. C. M. Palmer and J. McIntyre, Jarrow, Durham, ship builders. An improved mode of applying and fastening metal sheathing to the bottoms of iron ships or vessels, and to iron for other uses.

606. T. H. Morrell, Leyland, Lancaster, gentleman, and J. Williamson, Willcross, Gisburn, York, gentleman. A new or improved method of purifying the noxious vapours or gases given off from night soil or other similar substances during the heating, drying, or evaporating of such substances.

607. E. A. Wünsch, Glasgow, merchant. Improvements in treating seaweed, and in apparatus therefor.

610. E. W. Binney, 40, Cross-street, Manchester, gentleman. An improved lamp burner. (A communication.)

611. W. Clark, 53, Chancery-lane, patent agent. Improvements in the manufacture of sulphuric acid, and in apparatus for the same. (A communication.)

612. W. Hamilton, 13, Paternoster-row, advertizing agent. Improvements in means or apparatus for registering suitable for advertizers' purposes.

613. J. Craig, Weston-park, Shipston-on-Stour, Worcester. Improvements in apparatus for detecting and detaining thieves, and indicating the presence of fire.

614. W. L. Tizard, Birmingham, engineer. Improvements in manufacturing curvated armour plates and other iron work, and in machinery or apparatus employed therein.

Dated March 5, 1863.

615. W. Whittle, Smethwick, Stafford, mechanical engineer. Improvements in machinery for the manufactzre of nails.

616. T. Thornton, E. Thornton, and R. Thornton, Elland, York, manufacturers. Improvements in machinery or apparatus for preparing wool or other fibrous substances for spinning.

617. J. Clinton, 35, Percy-street, Tottenham-court-road, professor of music. Improvements in the construction of flutes.

618. W. Allen, cotton spinner, and W. Johnson, Newton Moor, manager. Certain improvements in machinery or apparatus for grinding "cards" employed in carding engines.

619. R. D. Dwyer, Manchester, engineer. Certain improvements in springs to be employed in the manufacture of beds, seats, or for similar purposes where an elastic surface is required.

621. W. Wells, Ryder's-court, Leicester-square. Improvements in horse-shoes and in the method of fastening the same.

623. S. H. Foster and T. Bunney, Leicester, and J. Anderson, overlooker. Improvements in means or apparatus for the manufacture of looped fabrics.

624. J. Miller, Upwey, near Dorchester, gentleman. Improvements in horticultural buildings and other glazed structures, part of which improvements is also applicable to ventilating other buildings.

625. E. B. Wilson, 5, Parliament-street, Westminster, civil engineer. An improvement or improvements in the manufacture of steel, and in the apparatus employed therein.

627. J. Howie, Hurlford, Ayr, North Britain, coal master. Improvements in the construction of the crossings of railways.

630. C. Clay, Walton Grange, Wakefield, York. Improvements in chain harrows.

631. J. Morris and T. Newton, 200, Upper Thames-street, zinc workers. An improvement or improvements in refrigerators and other like articles.

632. W. H. Buckland, Barge-yard, London, gentleman. Improvements in the mode of, and in the apparatus for, producing gas for illuminating and heating purposes, parts of which improvements are also applicable for increasing the illuminating and heating power of ordinary lighting gas.

Dated March 6, 1863.

633. M. Jourdin, Manchester, chemist. Improvements in machinery for engraving by means of electricity.

634. A. Cuthell, Skerton, Lancaster. Improvements in self-acting dampers for steam-engine furnaces.

635. A. W. Makinson, Westminster, civil engineer. Improvements in locomotive and stationary engines.

638. G. T. Bousfield, Loughborough-park, Brixton. Improvements in the manufacture of illuminating gas, and in apparatus employed therein. (A communication.)

639. D. W. Ransom, 24, Pembroke-place, Liverpool. Improvements in fixing artificial teeth.

640. T. Hancock, Birchwood, near Alfreton, Derby, colliery manager and coal merchant. An improved receptacle for gold or other coins.

642. T. G. Webb, Manchester, glass manufacturer. Improvements in the manufacture of articles of pressed glass.

643. A. V. Newton, 66, Chancery-lane, mechanical draughtsmtn. An improved construction of elastic carriage wheel. (A communication.)

644. W. E. Newton, 66, Chancery-lane, civil engineer. Improvements in the construction of metal casks, and in the machinery employed in the manufacture thereof. (A communication.)

Dated March 9, 1863.

646. R. Mushet, Coleford, Gloucester, Metallurgist. An improvement in the manufacture or treatment of pig or cast iron.

650. J. Haworth, Manchester, gentleman. Improvements in breaks for omnibuses and other carriages.

652. W. Inglis, Edinburgh, engineer. Improvements in steam boilers and engines.

656. J. R. Gorst, Liverpool, carriage builder. Improvements in carriages.

Dated March 11, 1863.

662. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in voltaic belts and bandages. (A communication.)

664. G. A. Fulton and J. Clyde, Stepney, gas engineers. Improvements in dry gas meters.

666. H. Wilson, Watling-street, engineer. Improvements in machinery for shaping wood.

668. A. Barclay, Kilmarnock, Ayr, North Britain, engineer. Improvements in locomotive boring and winding engines.

670. J. Werge, 379, Oxford-street, dealer in photographic and scientific instruments. Improvements in apparatus for indicating any regulated maximum or minimum degree of temperature. (A communication.)

672. J. Renshaw, Manchester, machinist. Improvements in machinery for dressing, raising, and brushing silk and cotton velvets, velveteens, cords, plushes, and other piled fabrics.

Dated March 12, 1862.

674. F. Buser-Kraushaar, 2, Thavies-inn, Holborn. Improvements in apparatus for winding, cleaning, measuring, sorting, doubling, throwing, and reeling silk, parts of which improvements are also applicable to like machinery for spinning, doubling, and twisting cotton, wool, and other fibrous materials.

PATENTS APPLIED FOR WITH COMPLETE SPECIFICATIONS.

Dated March 12, 1862.

678. E. H. Lomas, Rodney-wharf, Church-road, Battersea, Surrey. Improvements in the action of charger or measure for powder flasks, canisters, or other vessels.

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

From the *London Gazette*, March 24, 1863.

3038. W. Palliser. Construction of ordnance and projectiles to be used therewith.

3045. W. Dobson. Apparatus used in dressing lace or other fabrics.

3047. T. Bradford. Clothes wringer and mangler, applicable to pressing the liquid from clothes in the process of washing.

3056. T. C. and J. Eastwood. Apparatus for combing wool or other fibrous substances.

3057. J. Slack. Nursery swings and cots.

3057. R. A. Brooman. Apparatus for shunting trains. (A communication.)

3069. S. Roderts. Frames for containing stoppered bottles and jars.

3070. H. Morgan and J. Parkinson. Weighing machines.

3081. W. H. James. Steam engines.

3093. J. Arbòs. Generating certain gases for lighting and heating.

3094. P. H. Klein. Machinery for turning or shaping metals or other substances.

3097. C. W. Harrison. Looms for weaving.

3099. R. Brown. Warming and ventilating.

3103. L. Lenzberg. Apparatus for raising and lowering Venetian and other blinds.

3104. H. J. F. Marmet. Lamps.

3108. J. Arbòs. Generating certain gases for obtaining motive power.

3113. G. A. Buchholz. Manufacturing semolina and flour.

3120. J. W. Child. Working wool and other fibres.

3124. W. Bottomley. Machinery for stiffening woollen and other fabrics.

3127. J. Townsend. Damping and preserving vegetable and other textile materials and fabrics.

3133. C. Wagner. Strengthening, securing, and rendering more durable the soles or bottoms of boots and shoes. (A communication.)

3138. S. and C. Deacon. Tops, caps, and windguards for chimneys.

3143. C. De Bergue. Manufacture of metal reeds for weaving.

3154. E. Leigh. Cotton gins.

3165. A. V. Newton. Sewing machines. (A communication.)

3187. W. A. Waddington. Machinery for cutting wood.

3188. J. T. Caird. Steam engines.

3220. W. Clark. Apparatus applicable as a pump water meter, hydraulic motor, or a steam engine. (A communication.)

3241. A. T. Becks. Machinery for cutting or shearing sheets or plates of metal.

3249. H. Swan. Stereoscopic apparatus.

3254. G. Lewal. Hot air apparatus in cast iron or any other metal or substance, consisting of prismatic tubes, to be applied to chimneys with flues and heat conduits. (A communication.)

3263. E. B. Wilson. Railway wheels.

3314. W. A. Turner. Machinery for cutting or paring starch.

3318. I. Spight. Horse shoes.

3398. E. B. Wilson. Machinery or apparatus for forging and pressing metals and other substances.

3422. F. Parker. Carriages.

3462. J. H. Riddell. Cast metal or other pipes or tubes for conveying gases, fluids, or vapours, and in the mode of connecting such pipes or tubes.

3463. J. H. Riddell. Stoves.

3472. J. H. Johnson. Ingot moulds employed in the casting of steel and other metals. (A communication.)

3482. W. B. Adams. Railways and tramways.

63. G. T. Bousfield. Skate fasteners. (A communication.)

162. R. A. Brooman. Sulphate of soda. (A communication.)

184. A. Boubée. Casting or moulding articles in glass.

253. J. Platt. Rotary engines.

263. T. A. Weston. Coupling and break for transmitting or regulating or arresting motion.

399. J. C. Jeffcott. Production and generation of gases.

411. F. E. Walker. Breech-loading firearms.

412. J. Morgan. Embalming and preserving from decay human bodies and bodies of other animals, also pickling, curing, and flavouring animal bodies.

438. E. Strawson. Buttons which may be instantaneously attached without sewing.

489. J. P. F. Datichy. Steam engines.

505. W. Hooper. Insulating and protecting telegraphic wires and rods.

512. R. W. Thomson. Obtaining and applying motive power.

513. G. Bower and W. Hollingshead. Production and transmission of gas or other fluids.

517. F. A. Gatty. Printing and dyeing cotton and other fabrics.

527. H. H. Henson. Mats.

572. J. Penn. Escape or relief valves to the cylinders of marine and other steam engines.

579. J. W. Burton. Refining and purifying oils.

606. T. H. Morrell and J. Williamson. Purifying the noxious vapours or gases given off from night-soil or other similar substances during the heating, drying, or evaporating of such substances.

608. P. Adie. Measuring angular and actual distances.

618. W. Allen and W. Johnson. Grinding "cards" employed in carding engines.

631. J. Morris and T. Newton. Refrigerators.

638. G. T. Bousfield. Illuminating gas. (A communication.)

678. E. H. Lomas. Charger or measure for powder flasks, canisters, or other vessels.

The full titles of the patents in the above list can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners' office particulars in writing of the objection to the application.

LIST OF SEALED PATENTS.

Sealed March 20, 1863.

2593. T. Knowles, J. Houghton, W. Knowles, and W. Houghton.
2595. W. Dobson.
2597. R. A. Brooman.
2604. R. A. Brooman.
2614. F. Tolhausen.
2615. J. Raywood.
2616. J. R. Breach and E. B. P. Smith.
2617. J. Eardley.
2618. W. Lea.
2623. T. R. Harding.
2625. J. J. Bates.
2629. W. E. Gedge.
2635. J. C. Pruvost-Bauchard.
2643. H. Hirsch.
2645. H. Ellis.
2657. P. G. Van der Byl.
2661. W. C. Cambridge.
2663. W. H. Ward.

Sealed March 21, 1863.

2334. S. J. Paris and W. Bate.
2640. W. B. Lord and F. H. Gilbart.
2648. R. A. Brooman.
2683. J. E. Billups.
2695. D. Lowe.

MECHANICS' MAGAZINE.

LONDON, FRIDAY, APRIL 3, 1863.

RIFLED AND SMOOTH-BORE GUNS.

THE experiments at Shoeburyness on Captain Inglis's gun-shield furnished results which gave rise to some interesting comparisons between the effects of rifled and smooth-bore guns. On this subject a practical artillerist has furnished us with data and calculations on some points of interest which it is desirable should be submitted to public discussion. He takes as the basis of his calculations the effects produced by projectiles fired from three guns—namely, a Whitworth hexagonal 148-pounder, an Armstrong spherical 100-pounder (smooth-bore), and a Lynall Thomas rifled 150-pounder. Each shot was fired with a charge of 25 lb. of powder, and their respective impact velocities, in the order we have named them, were reported to be 1240, 1470, 1150, but we believe the last was 1215 feet per second. Our informant states that the shooting on the whole gave results very much in favour of the rifled guns. The values of the impacts being in proportions as follows:—

Whitworth rifled	100-pounder smooth-bore	L. Thomas rifled
17·08	14·99	18·34.

The effective forces, measured by multiplying the weight by the square of the velocity, he states to be:—

Whitworth	100-pounder	L. Thomas
21·06	22·13	22·29.

The windage of the three guns he estimates thus:—Whitworth, *nil*; Armstrong, 100-pounder, almost nothing; L. Thomas, ·092, which last is said to be an "enormous superiority."

On these calculations we will make some remarks. The value of impact cannot be determined unless the diameter of the shot, the material of which it is made, the quality and thickness of the plate, and the backing of the plate are the same. A cast-iron shot will make a deeper indent than a wrought-iron shot, but the effect of the former will be less damaging, because the metal breaks up at the moment of impact. The momentum is divided amongst the fragments, many of which recoil from the mass without coming in contact with the plate, consequently the projectile does not produce its maximum effect. The results with a hardened wrought-iron shot would be somewhat similar. A softer and tougher wrought-iron shot would make a less indent, and have less penetrating force; but its smashing effect would be greater, because, remaining entire or nearly so, the momentum of the mass at the moment of impact would be concentrated. A tough steel projectile would be superior to all.* If one shot be smaller in diameter and the work done (measured by the weight multiplied by the square of the velocity) be the same, the smaller diameter will produce a greater indent than the larger, by the reason that the same force is concentrated in a smaller area. If one plate be thinner than another, or the backing to one be a yielding and to another a rigid material, the indent, in each case, will be greater in the former than in the latter.

With reference to windage, we have to take into account the discrepancy between the bores, which disturbs fair comparison founded on similar charges of powder. Every gun is made to produce its maximum effect in its normal condition, which consists in a systematic and proper apportionment of strength of the gun, diameter and weight of the projectile, and charge of powder. Alter either of the two latter conditions, the gun loses a part of its calculated effect.

Armstrong's 100-pounder was fired with 25 lb. of powder, its service charge being 33 lb. This was a disadvantage; and yet its superiority to Whitworth's was as 22.13 to 22.06, and it only differed from L. Thomas's as 22.13 to 22.29.

The statement that the windage of the Lynall Thomas gun was greater than that of the 100-pounder, does not rest on a sure foundation. The exact windage of his gun is given as .092 inch. It could be measured, but that of the 100-pounder could not—at all events, it was not, and is stated to be "almost nothing," because the fit to the bore was so close that the shot was with difficulty introduced into the gun. But this does not prove the windage to be less than .092, it may have been more. The difficulty of turning a perfect sphere is well known. The slightest deviation from the spherical form at one point, might render it difficult or impossible to ram the shot home, and yet there might be a large amount of windage at other parts. A cylinder can be turned with perfect precision—so true as to make a close fit all over. The Whitworth shot are only partially hexagonal. They are not now intended to be a close fit. The angles of the hexagons on the shot are removed, but they remain in the rifling. Hence the open spaces at every angle cause a great amount of windage. We are told that the friction in the mode of rifling the Lynall Thomas gun is reduced to the minimum, and the rifling itself is of a form to come out of the gun as true as a die. Hence there is absolutely no deflection, and the superior results are accounted for. We are not prepared to gainsay these statements, but they remain to be proved by a series of experiments.

As to the form of rifling, it does not alter the character of a rib in relief on the bore. The rib has to resist laterally the whole force of the pressure of the grooved shot in twisting out of the gun. This pressure is constantly on one side of the rib, wearing it away, and tending to force it off the face of the barrel.

Some time ago Mr. Anderson (of Woolwich) made a course of experiments to ascertain the strength of different forms of rifling. These, it is asserted by our correspondent, tended to show that the Lancaster was the weakest and the Thomas the strongest, the latter being the only one which broke the machine in the attempt to destroy the grooving. This mode of testing the strength of systems of rifling with a machine is fallacious, it is not the right mode—it is not the same as explosive force. The resistance of a rib, in the rifling to pressure on its top, from within the gun outwards, would differ essentially from lateral resistance of the rib to the friction of the shot when the gun is fired. No doubt, a steady force pressing on the rib, such as that of a wedge driven into the muzzle of the gun, would encounter great resistance from the rib in relief, more resistance than from a grooved or an oval surface; but that kind of resistance is not the same thing as resistance to the explosion of gunpowder which searches out the weakest place and will find it. Of all systems of rifling, or of boring guns to produce the effect of rifling, we cannot but think the oval bore must be the strongest, because it deviates, in a small degree only, from a circular bore, is a continuous curve, and requires no lines or grooves to be cut into the metal. It is, in fact, an oval smooth bore.

We do not make these remarks in a controversial spirit. Our only object is to elicit the truth; and we make no doubt, as the points referred to are of moment with reference to the best class of great guns, and the best form of rifling, they will be fairly discussed by the advocates of the various systems, which the important experiments about to take place will soon bring before the public.

TRACTION ENGINES.

WE once, foolishly we admit, believed that the days for sumptuary laws had passed away, but truly "old things become new;" and as Queen Mary passed laws regulating the width of the toes of her subjects shoes, so does our own Government pass laws regulating the breadth of our wheels; doubtless, both laws were enacted from equally good reasons. Mary's subjects submitted quietly enough, we dare say. "That was the law," and that was enough for them; but, unfortunately, engineers as a class are so much accustomed to demand a reason for everything, that they demand a reason for the very laws which touch on their profession or interfere with their manufacture; and although Mary's subjects might submit quietly enough, engineers of the 19th century will feel little disposed to bow to a law calculated to do them an injury, and interfere with a branch of their business growing daily of more importance.

The 3d clause of the "Locomotive Act," says that "every locomotive drawing a waggon or carriage shall have a breadth of not less than 9 in., and the wheels of every locomotive shall be cylindrical or smooth soled," under a penalty of £5 for every day any engine infringing such Act shall be at work. From this, we see that we are compelled to adopt a tyre, not less than 9 in. wide, without roughness or projection, gap or opening, and this law is sweeping, minute, and absolute. An Irish barrister once said that "he could drive a coach and four through an Act of Parliament." It is quite certain that, were he now alive, he could not perform the same feat with a traction engine; we scarcely wish to assert that the law is unjust, illiberal, or injurious in its tendency, not only to the country at large, but to a very large class of enterprizing individuals. We prefer rather to place facts before our readers, and ask them to judge for themselves; and in this spirit we will try to show the precise bearings and effects of a clause, to which we wish to attach no epithet, and in as few words as may be.

Most, if not all, of our readers are aware that the wheels of a railway locomotive are made of iron, generally wrought, in a few rare instances cast iron. The best material for the wheels of a common road locomotive also is wrought iron; wood has been used, but quickly becomes unserviceable; cast iron is unsuitable from its great weight, induced by any attempt to make a serviceable wheel. Wheels are, it is true, made partially of cast iron; but we believe that both purchasers and builders will, ere long, find it their interest to make their wheels almost wholly of wrought iron.

Now a 6 ft. driving wheel for a road locomotive, is a very different affair from a 6 ft. driving wheel for one of its brethren of the rail. In the latter, the width of the tyre is small in proportion to its thickness; and from the mode of manufacture, rendered necessary to secure great accuracy of shape with the maximum degree of strength, its expense is very considerable—so considerable, indeed, that any attempt to construct the wheels of a traction engine even on a modification of the same principle is quite out of the question.

---

* Experiments at Shoeburyness by the Ordnance Committee, reported since this notice was written, prove the greater penetrating force of steel over cast or wrought iron projectiles. Several shots made of a tough and hard steel by Messrs. Makin and Sons, of Sheffield, which were fired at a "Warrior" target, penetrated a 4½ in. plate, and caused an indentation nearly 50 per cent. deeper than either the wrought or cast iron missiles, and produced a much greater effect on the target generally.

The wheels for a road locomotive are different in every respect; in these, we require a very broad tyre to suit the comparatively soft road; rigorous accuracy of construction is unnecessary, and would be useless; in consequence, a totally different mode of construction is adopted. Instead of welding together the component parts of the wheel under the steam hammer, as in the railway locomotive, the wheels of the traction engine are almost invariably built up, piece by piece, and fastened together by rivets; a mode of construction found safe, serviceable, extremely convenient, and sufficiently economical.

We have already stated that the tyres of such wheels are thin; and overhanging the spokes, as they do at each side, from their great breadth, it is obvious that a few days' use would render them polygonal rather than circular, as the rim would flatten between the spokes; in order to avoid this, strengthening pieces, or "strokes," as they are termed, are fixed round the outside of the tyre proper. The general arrangement of these strokes is a point on which much difference of opinion exists; the best practice places them in two rows, side by side, round the wheel; they are made in lengths, generally of about 2 ft., and from 3 to 5 in. wide, and are of course firmly rivetted together on the tyre. Not only do these strokes then strengthen the tyre, but they also serve the scarcely less important purpose of protecting it from wear; they are themselves easily replaced when worn out, while replacing a tyre is rather a serious undertaking. The general practice is to leave a space of about 3 in. between the ends of these strokes, such spaces proving of the utmost value in retaining the clips or spades put on when the traction engine has to cross turf, which smooth wheels can hardly accomplish.

Now it is scarcely possible to construct a suitable wheel, lighter or more cheaply than the one to which we refer, but the Locomotive Act renders the use of such a wheel absolutely impossible, if the law be vigorously enforced, unless the proprietor feels disposed to pay £5 a-day for the privilege; and the worst and most injurious characteristic of the clause is, that it will accept no equivalent for the 9 in. of smooth sole. In one of Hogarth's pictures, we see an electioneering party bearing a banner with the inscription, "Give us our eleven days;" the authors of Vic. 25, cap., exclaim, with equal pertinacity, "Give us our 9 in.;" it will not suffice that we may have even double the area of tyre surface resting on the ground at one time. According to the framers of the bill, two 7½ in. tyres are far more injurious to the road than one 9 in. with a double load; and the effect of this is, that as a single 9 in. stroke will not effectually protect a 12 in. tyre. Besides greatly increasing the first cost of construction, builders of this class of engine must either submit to have cast-iron tyres, or use wrought ones of great thickness, costing about three times as much as would otherwise be necessary.

We have not yet alluded to the question of adhesion. We believe that the bearing of the bill on this part of the subject is of even greater importance than on the practical difficulties and annoyances entailed by its rigid enforcement on the wheel-maker, little, perhaps, in themselves, but great in the aggregate.

We have no doubt that the framers of the clause intended to prevent injury to the roads. They may feel surprise when we inform them, that there is nothing so likely to injure a road as a smooth wheel; its capabilities for doing mischief far exceed that of the rough wheel in general work; the reason is obvious enough. The only injury a traction wheel can do to a road, apart from that common to the rolling action of all wheels, is by slipping. It is evident enough that so long as a tyre is so moderately loaded in proportion to its bearing surface, that it does not sink into the road, that its rolling action can do comparatively no harm; but so soon as such a wheel begins to slip, it will cut, or rather grind away the road.

It is quite as much the wish of the engineers to avoid this slipping as it is the desire of the legislature to prevent the consequent injury to the roads; but instead of permitting the use of a rough surface, to prevent this slipping, and consequent abrasion, the latter compels the former to resort to a smooth wheel, which exerts an attracting action almost continuously. Be it remembered, that we do not for a moment advocate the use of spikes, spades, &c., on our highways; such means of obtaining adhesion are, except in a very few cases, not only unnecessary, but positively inapplicable, whatever theorists, who are only acquainted with the road locomotive on paper, may imagine. Half-a-dozen semi-spherical steel rivet-heads projecting half or three-quarters of an inch from each square foot of the tyre, will give an ample amount of adhesion for all ordinary purposes; wheels so provided, 12 in. wide, and each loaded with 3 tons, possess quite sufficient adhesion to draw 20 tons up an incline of 1 in 15 or 20 without slipping, and will injure the road so little that they will scarcely leave a mark to show where they have gone; it has been urged that the use of all such projections must dig up the road on the same principle as the rotary digging machine; such an assertion is simply absurd; did the wheels slip they would certainly injure the road more than a smooth wheel, but such roughness effectually prevents slipping; and so long as a wheel with projections of such moderate length continues to roll, it can do little injury; indeed, we must recollect that the road is not smooth; on the contrary, every part of it is rough, and full of inequalities; and into these hollows and inequalities, such projections as we speak of fit without necessarily injuring the road in the slightest degree.

We do not pretend to assert that traction engines are absolutely harmless; we do not wish to maintain, with some, that they actually improve a road; but we maintain that, for the transportation of heavy goods, at moderate speed, they exert a far less injurious action; it is easy to see that a cavalcade of fifteen or twenty horses with spiked shoes must do more damage to a road than a broad wheeled traction engine transporting the same load, the projections on whose tyres need not be greater than those on the horses' shoes. So far from digging up the road, these projections make but a slight indentation; with a properly smooth wheel the case is different; such wheels slip almost continuously, and being always as heavily loaded as possible, in the attempt to obtain adhesion, woe to the road on which they are at work. We have seen a furrow ten yards long left by such a wheel, where a rough one would scarcely have marked the place where it passed.

We thus see that this clause is calculated to defeat the end it had in view by its framers, and that it bears so injuriously on the construction of this class of engine that it amounts almost to a prohibition of their use, and prevents in consequence the further development of a principle likely to add very extensively to our resources of transit. We believe that the matter only requires to be placed before the public in its proper light, to obtain such a readjustment of the existing law as will prove satisfactory to all parties.

INSTITUTION OF NAVAL ARCHITECTS.

The ordinary meetings of this institution took place last week in the large hall of the Society of Arts. A large number of members, associates, and friends were present. The Right Hon. Sir J. Pakington, occupied the chair.

The following is merely an abstract of some of the principal Papers read and discussed. On Thursday morning four Papers were read in succession upon the great subject of iron-clad ships—by Mr. W. Fairbairn, "On the Construcof Iron-plated Ships;" by Mr. Samuda, "On Iron-plated Ships;" by Mr. Scott Russell, "On the Present State of the Question at issue between Modern Guns and Iron-coated Ships;" and by Mr. E. J. Reed, of the Admiralty, "On Ironcased Ships."

Mr. Fairbairn's Paper had reference chiefly to the importance of the working of the iron, and the methods of obtaining the greatest mechanical strength. As a rough statement it might be said that thickness of plate would represent strength, but much depended upon the processes of hammering and rolling, by which the fibre and texture of the metal were improved. He recurred to the views he had expressed in former Papers, which were founded upon many experiments, and said that the cellular structure employed in tubular bridges and girders was the best form for obtaining greatest strength. He advocated the use of this principle in the construction of iron ships, and would have the cellular compartments run the whole length of the bottom and sides of a ship, her armour plates to come above this, and the decks to be made very strong means of support by making the beams of iron. A ship ought to be so stiff that she would bear suspending on two points, one at each end, or even upon one amidships. As to steel, it was difficult to say what might not be done with it, as its strength was much greater than that of iron; still, as yet it had not been sufficiently tested. He was not inclined to building very large ships. He showed a diagram of a vessel in which he would arrange the heavier burden of engines and guns in the middle, and these to be protected with more extensive armour-plates, while a belt might be carried round the ship at the water-line, covering the steering apparatus and screw, but leaving parts unprotected. As to large guns, he was much of opinion that the limit of their strength had been attained in the 300-pounder.

Mr. Samuda's Paper commenced by stating that an efficient navy was and must always be of the first importance to this country, and that no navy could be efficient except it be armour-cased, in order to meet all artillery that might be brought against it. Partial protection was no longer upheld as a necessity, and entire protection, in deference to a strongly-expressed opinion of its necessity, had been substituted in all the vessels that had since been commenced. Entire protection, the greatest speed obtainable, armour which admitted of the easiest replacement, and, lastly, which added strength to the vessel by being incorporated into its structure. Those four points could not be too frequently urged as indispensable to an efficient iron-clad navy. Although he held that plating wooden ships in armour was but a make-shift, and that real service and bad weather would lay bare the fallacy of expecting it to be anything but a temporary job, yet he felt it was satisfactory to know that some proper amount of protection was about to be given to the country, even though it should be limited to the Government dockyards. He could not help expressing the surprise and indignation he felt, in common with other leading shipbuilders, who had all contributed most loyally to advance the success and welfare of the navy, and who had not hesitated to place themselves and their establishments at the disposal of the Government without any adequate profit, when the construction of the iron navy was of imminent importance, to find themselves referred to by the Controller of the Navy and the Admiralty in terms of censure and reproach, as a reason for the asking Parliament to give back to them the privilege and patronage of again building in their dockyards vessels which had far better have been built of iron than of wood, and in private instead of in public dockyards. The period had arrived when they must consider whether any and what general improvement in the character of those which would have to follow should be adopted, and a consideration of the relative advantages of portholes and cupola ships would lead to the solution of that important question. The cupola reduced materially the weight of armour required to be carried on the top sides of the vessel. If 4 ft. be fixed in both cases as the extent of under-water protection, the cupola vessel only required a total depth of armour of 11 ft. against 20 ft. for the porthole. The 11 ft. gave perfect protection to the cupola vessel, while the 20 ft. only yielded partial protection to the other, every porthole being assailable by shot and shell. The next advantage was the facility of working very much heavier guns, the advantage of moving them mechanically, and the very much greater range obtainable rendered every gun in a cupola ship at least equal to two worked in a porthole ship, and in many instances to much more. Another advantage was the concentration of the crew, and their extra protection in all circumstances. Also the rolling of the vessel would interfere with the working of the guns, where they had to be fired from ports, long before it would have reached a pitch to prevent working them in cupolas, and where they were fixed from over decks; and, lastly, the power which that mode of keeping down the tonnage of the vessel, and at the same time obtaining a high velocity, was of the greatest importance. The importance of obtaining that result at an early period was what he desired; and if he could sufficiently engage attention to the importance of that conclusion, he should have obtained the object he had in view in writing that Paper. The "Prince Albert" was an excellent beginning, having many advantages, but it should have 800-horse power instead of 500, and that change would make it a 13-knot ship, and much improve the character of the craft. He suggested that the Admiralty should build five additional "Prince Alberts" in private yards at the same time they were proceeding with the five porthole frigates in the dockyards. The cost of the whole of those vessels would be only £1,000,000, and he was sure the House of Commons would vote it for such an important object. The result, he believed, would be that the cupola ships, far from being useful only for coast defence, would be found serviceable all over the world.

Mr. Scott Russell reminded the society that they were considered heretics two years ago for advocating iron ships. The question had progressed since then, and now the demand for the new navy was for ships with great speed and immense strength. They must be 14-knot ships; they must be long to have speed, and broad to have stability, and keep their ports 9 ft. out of water. He put the case of there being an "Alabama" upon the track of our China and Australia trade; he would not call her a pirate, but supposing such a ship in time of war, we had only two ships that could chase her—the "Defence" and the "Resistance," would only follow in her wake. We saw the whole available American navy engaged in trying to catch this "Alabama." Mr. Russell would do away with the timber-backing of the "Warrior," and substitute iron plates. It did no good; it only caused buckling of the plates, tending to draw out the bolts, and took fire with shell, as we saw at Shoeburyness. The weight of this wood would be better exchanged for iron plating. Mr. Russell gave Mr. Pole's formula for the relative strength required for plates *versus* guns. For—

68 pounder	4½	inches
130 „	6½	„
200 „	7½	„
290 „	8½	„
400 „	10½	„
500 „	11½	„
600 „	12½	„

We have now to provide against a 300-pounder sending shot with a velocity of 1,500 ft. per second, and we have to mount and fire this gun rapidly and easily to the ship ourselves. He could not but think that this would be done with all the able mechanics and engineers the country possesses. Captain Coles's cupola he had made himself, and this one had been tried successfully. The turntable was the only mode he knew of which enabled such heavy guns to be moved with so much ease; and by this means, too, the weight was kept in the central line of the ship. The "Prince Albert" he could not think a judicious application of the principle, and the "Royal Sovereign" was much worse. But give any one of our gallant naval officers a 15-knot ship, with a cupola forward and one aft, and the engines and rudder shot-proof, and he would be bound they would give a good account of any "Alabama" in the world. But if it was required to work guns even on the broadside by machinery, it was only to say so, and there were plenty of mechanics who could do this. Mr. Russell intimated that he knew how to make a larger number of guns available than in a cupola. He could see how the 300-pounder broadside gun could be put on a par with the turntable 300-pounders. The portholes in the cupola have the great advantage of being small, but it would be quite practicable to work a 300-pounder at any elevation in an opening which shall not be larger than the muzzle, only sufficient to allow of aiming. As to weights of armour, he would expect to see used 7½-inch plates, with 3½-inch iron backing, in vessels 500 ft. long and 70 broad, of 12,000 or even of 22,500 tons—"Great Easterns," in fact, 700 ft. long and 83 broad. Mr. Russell pointed out that the "Hector" and "Valiant" are not proof against shell at unarmoured parts; they would be blown up by shell entering here. But we must adopt expedients of partial protection and partial battery. The "Warrior" has more iron in her than the "Great Eastern," in consequence of it not being used with economy. Protection to the waterline he did not much care about, as the water-tight compartments serve the purpose of protection. He attributed much to the labours of the Iron-plate Committee, and looked to next year to show us how much progress had been made in scientific knowledge and professional acquirement, and ended by saying that engineers and naval architects were ready to serve the Government, and to put up with loss rather than the service of the country should suffer.

Mr. Reed then followed with his Paper, which, after a few observations alluding to his having resigned his office of Secretary to the Society so as to avoid embarrassing them, referred chiefly to a defence of his plan of construction adopted in the "Enterprise" sloop of 950 tons, and an attack upon Captain Coles's cupola plan. His iron-cased ship was as unlike the "Monitor" as possible; it was well out the water, well supported at every part, the armament in the centre, of few guns of long range, with the steering apparatus and engines protected by proof armour. He would armour-plate every ship of every size to a certain degree, giving them large guns with long range and high speed. Anything like the "Monitor" would be a decadence, a disgrace to our pride and to the "flag that has braved the battle and the breeze." The form of our ships should never be compromised as it is in the cupola plan. They must have good handsome masts and rigging. He advocated wooden ships, and especially wooden bottoms in small ships particularly. But if 14-knot ships must be had, then iron is the only material to make them of; and this was according to the first design he had the honour of submitting to the Admiralty. He stated the evidence of the Surveyor of Lloyd's, that in some iron ships not five years old 1,000 rivets had disappeared in the bottoms. And in private yards he knew of the plates being joined so badly as to require caulking, as the records of the society, he believed, would show. Still he would not deny that now no labour or capital is spared in private yards, and a high degree of excellence is attained. Mr. Reed described the "Enterprise," and said the frame of this ship was of timber converted. She had her battery in the centre, in a water-tight compartment, with means for fore and aft firing of the guns. In the "Renard" and "Favourite" the iron upper work was avoided, and they were completely plated. He alluded to the severe criticisms his plan had met with from the press, and especially from Admiral Halsted, defending the "Enterprise" from the charges brought against her in that gallant officer's pamphlet. As to the cupolas, or turrets rather, of Capt. Coles, they were exposed on at least 10 ft. square on all points. The trials with the "Trusty" in 1861 he thought not conclusive, as breech-loaders were used. Then these cupolas could be easily wedged by boarders. He could see no prospect of such vessels being made sea-going, and in action, as the bulwarks are permanent, the guns could not be fired fore and aft. By an array of figures on the black board, Mr. Reed showed that the statement in the Mechanics' Magazine, 27th February, as to the weight of broadside being in favour of the cupola, was not only erroneous, but that the advantage was largely in favour of the "Favourite." Guns of 20 tons he expected to see worked by machinery, and if we disponsed with these 120-ton turrets we could afford to use machinery. Small shield ships could not be constructed; and as to the ships now proposed by Captain Coles, it was impossible to construct them as designed. Rapid turning of a ship with broadside ports like the "Favourite" would be gained by using the double-screw system and high speed; experiments upon which had recently been successfully made by Captain Astley Cooper Key. He did not regard the "Enterprise," "Resolute," and "Favourite" as specimens of the class of ships he conceived would become the future style of naval architecture.

Mr. Fairbairn stated that he had proposed in 1855 to the Admiralty to investigate the subject of iron plates for ships, but was not encouraged to proceed.

Admiral Halsted, in reply, admitted that he was mistaken as to the statements in his pamphlet about the "Research" having the iron box, as he called it, or rectangular cupola. He protested, however, against being provided with these ships-of-war, one-third of whose guns were useless, and maintained that no trials had ever been made of targets representing ships' sides until the ships were in progress of construction. The Whitworth shell, fired upon a target stronger than the "Minotaur," in November last, had initiated a revolution in naval gunnery and shipbuilding, and henceforth it was shell that was more difficult to keep out than shot, for it penetrated with more facility than solid shot.

After the discussion, Mr. Lancaster, the well-known artillerist, stated, in reference to the future use of very large ordnance with shell, that he had seen in America lately 400-pounder shells, of cylindrical form and hollow-headed, fired from an 18-ton gun, which pierced plates of 9 in. thick at long ranges. These guns were used in turrets, to which was attached a lower and smaller turret, in which the loading of the gun was managed by the crew of the gun; and this was much facilitated by using a small tramway, on which the gun worked.

At the meeting of the Institute on Friday, Sir J. Pakington in the chair,

Captain Cowper P. Coles described his plan of turret ships, especially comparing with the "Favourite" (a vessel on the plan of Mr. Reed), his own design, called the "Naughty Child," being a ship of the same length, beam, and tonnage, and of equal power, speed, and draught of water. In the "Favourite," the guns are at the two sides of the vessel, and are placed in a protected battery amid ships, having a very limited range, and being in danger of dipping into the sea on the roll of the ship. In the "Naughty Child" he proposed to place a smaller number of guns—say three in two cupolas—which guns, from the facility of turning round the turret, would be as effective as a broadside twice the number. In the cupola, also, he had the advantage of keeping the gun pointed in the right direction, so that no time was lost after loading, but fire might be delivered at once. The same facility existed for keeping the guns pointed at an enemy while manœuvring the ship; while, in case of boarders, he could fill the spaces between the masts and stays with riflemen, as well as the tops of the turrets. The danger of the turrets being damaged by shot was not great. Sixty-nine shots were fired at the Trusty, by the best gunners in the navy, and only 44 hit the cupola. It was a great advantage of this plan, that by it guns could be trained and loaded at the same time. He read an extract from an account of a recent fight in America, showing that no injury had been sustained by the turret ships, although in one case the turret had been hit sixteen times, and that the guns were perfectly manageable. He said that the danger of wedging the cupola was small, and he thought little difficulty would be found in knocking out the wedges if the enemy succeeded in driving them in. He contended that the proper vessels for us would be shield-ships, with a belt of armour reaching five feet above and below the water-line, armed with a small number of heavy guns in cupolas.

Mr. Reed objected to estimating the force of a ship by the weight of its broadside. Round shot should not be compared with elongated projectiles. At Shoeburyness the 150 lb. round shot produced nearly the same effect as the 300 lb. elongated. It was not fair to deceive the public by such comparisons. He hoped that this discussion would have the effect of making gentlemen careful that their facts should be unimpeachable.

Admiral Halsted asked how a broadside ship such as the "Favourite" could be defended as well as a cupola ship like the "Naughty Child," without using double the number of guns to produce the same effect.

Admiral Sir E. Belcher said that in the "Naughty Child" the guns were not in the centre of the turntable, and when the guns were on the lee side they must tend to prevent the ship from righting herself, while the guns on the two sides balanced each other. He had proposed a plan of three guns on one turntable, each placed at right angles to the radius, so that the recoil of one gun would bring the other into position.

Mr. Prideaux sketched on the board the outline of a plan he had submitted to the Admiralty of a ship which appeared something like the cigar-shaped vessel they were building in Liverpool some years since.

Captain D'Orsay said draught of water was an element of little importance in the inquiry. We should build the best ships, no matter how deep they were. The effect of weight depended on its distance from the centre of gravity. Now the guns in the turret were nearer that centre than those on the broadside. Another great advantage was that they could be fought at longer angles, having a range all round the ship. In rigging, it was well known that the more rigid and unyielding it could be made the better, and he thought the tripod masts a great improvement.

Captain Scott said that a cupola ship must be unequally trimmed if she wants to give full effect to her broadside. The loss of a few plates of armour would throw the vessel up on the side next the enemy, and elevate the guns out of range. He did not think that the turrets allowed room to work the guns, and on the whole considered the plan of the midship battery the best.

Mr. Scott Russell said we should not pit the vessels against each other, but build both, and put them each to its right purpose. There was not really much difference between the two ships; both could carry armour on the water-line and for 5 ft. above it. Captain Coles placed the remaining spare weight in his ship in the form of cupolas, &c., and Mr. Reed placed it in that of a battery amidships. Were the cupola and guns heavier than the battery and guns? He thought they were at least as heavy. The heights out of water must be equal. The form most favourable for Coles's plan was a vessel with only two cupolas, which was as to these conditions on a par with Reed's ship. Then the differences were, that the latter could fight both sides at once, while the cupola ship should turn round her guns. To balance this disadvantage, Captain Coles could train his guns while loading, and could keep them on an enemy while moving. This was a great advantage. When he came to consider a vessel with a greater number of turrets than two, he thought the broadside ship had the advantage, but he said we ought to build both kinds, and do our best.

The Chairman said he must congratulate the society on their having held a very interesting and instructive discussion, which had been conducted with great good humour. He would not presume to express an opinion; but he thought the case was like what happens in many families, where the favourite is apt to be a naughty child. He called attention again to the tripod masts, which he considered a great improvement, as with rope rigging it was only at the weather side that it acts, while on this plan the one side was a stay, and the other a prop.

This closed the discussion on the shield-ships.

The concluding meeting of the members of the Institute was held on Saturday, the President, the Right Hon. Sir J. Pakington, Bart., M.P., in the chair.

Mr. Scott Russell read a Paper on the "Education of Naval Architects in England and France." He commenced by comparing the state of naval architecture in England and France, and the means taken by the Government of the latter country to found, foster, and encourage a naval school of architecture, which had been found to work with the most admirable results. Little had, he said, been done in England to take the best means of educating men for that science; and it was only after considerable outward pressure some years back, that the Government had decided in founding a Naval School of Architecture. This was done, and a few students admitted; but in 1853 it was abolished by Sir James Graham, who was at that time First Lord of the Admiralty. It might naturally be asked how this had occurred, which could very easily be answered, as it was found that the Government had broken faith with the students of the school in every particular; and they discovered, after having made a sacrifice of some years of study, and made themselves efficient naval architects, that the Government declined to employ them, and there was only one instance in which the Government had given proper employment to one of the pupils, while all the rest who were competent naval architects were sent to the different dockyards as supernumerary draughtsmen. This was not in consequence of a want of scientific knowledge on the part of those gentlemen, as they all bore certificates of competency; in fact, the pupils of the School of Naval Architecture, although their talents had been to a great extent ignored by the Board of Admiralty, had since, by their own exertions and scientific knowledge, all obtained high positions as naval architects of the first class, and to them was due the credit of altering the sailing fleet into a steam one in a short space of time in a pressing emergency, by that fully repaying the cost of their education. In the case of those pupils of the school, Messrs. Chatfield, Crease, and Reed had written a report which he considered as a model of systematic naval architecture at that date. Those gentlemen had been given a chance to show what they could do; and the vessel they built, although their first, had every quality for which it had been designed. He then gave an account of the great progress France had made during the last ten years, both in the science of shipbuilding and manufactures, in which up to the present time we thought we were supreme, and instanced the way in which a great French Steam Navigation Company had driven the Peninsular and Oriental Company out of the Mediterranean trade, and had in addition commenced an opposition by running magnificent vessels to China. He also mentioned as a fact that the Belgian locomotives had not only shut out the English ones from the continental markets, but that they were now brought over to England and undersold the English manufacturers. He concluded by regretting that at the present time the English were obliged to go to France to receive what he considered the requisite education on naval architecture, and strongly advocated the formation of a school or college of the kind, assisted by the Government, and explained the way in which it could be carried out.

Mr. Chatfield spoke, as one of the pupils of the School of Naval Architecture, of the efforts which had been made to put the school in the position it should occupy in this country, which were foiled and annihilated by Sir James Graham, who put them all aside for the purpose of introducing Sir William Symonds as Surveyor of the Navy. He was, however, succeeded by Sir Baldwin Walker, who frankly admitted that he was not a shipbuilder, and his doing so was the means of placing the most competent naval architects of the abolished school at his elbow—men who thoroughly understood the subject, and whose designs were carried out, although they did not get the credit for them. He approved of Mr. Russell's plan for founding a school of instruction on the subject, and agreed with him as to the necessity for it. He at the same time denied that any very great credit was due to the French for any designs sent to this country, as they had not been adopted. In fact, their pupils were in the habit of coming to the English dockyards for instruction in their profession, and often went back as competent architects, having carried with them the ideas of the practical men of our own dockyards, and taking credit for the designs they had seen here as their own.

Mr. Samuda disagreed with Mr. Russell as to the desirability of establishing a college for the sole purpose of instruction in naval architecture, as he thought the education received at an English college was sufficient until they came into a practical shipbuilder's yard.

Rear-Admiral Sir Edward Belcher said he would have hesitated to occupy the time of the meeting had he not received some information on the subject during his business connection with Sir R. Seppings, Sir Wm. Symonds, and Admiral Hay, from all of whom he had acquired some valuable information, in addition to some sound practice which he had himself acquired during his professional career. He then went into the question of speed, and compared some of the old line-of-battle ships with those of the present day, and claimed a rate of speed for the "Winchester" while under sail which had never been equalled by a man-of-war steamer—namely, seventeen knots. He also mentioned the "Southampton," "Warsprite," and "President," the latter having been rebuilt after capture from the Americans, as ships of unequalled speed, which had beaten the best French vessels in all points.

After the meeting had been addressed by Dr. Woolley, Mr. Grantham, Mr. Reed, and others,

The Chairman said he was disposed to believe that Mr. Russell was right that England was not in the position that it ought to be in a scientific point of view. All countries had, he considered, gone greatly ahead, in some cases eclipsing the English, and he advised them all to follow and consider Mr. Scott Russell's proposal, and strike out and adopt, after careful consideration, some plan of the kind which would give practical effect to the views so ably laid before them, in which he would co-operate in every way in his power.

Mr. Ditchburn, M.I.N.A., then proceeded to read a Paper "On the Origin and Construction of

Her Majesty's Yacht 'Fairy,'" but after having read a portion, he, at the suggestion of the chairman, withdrew the Paper, as it contained some strictures on the professional knowledge of a chief constructor of the Royal navy who is now living.

Mr. Gladstone, C.E., read a Paper "On an Instrument for measuring the Strain on Ships' Cables;" after which Mr. W. Froude, Assoc. I.N.A., read a paper "On a curious form of differential Wave in a stratified Fluid," with an experimental illustration.

An expression of thanks having been given to the chairman before retiring, and also to the secretary, who found that certain duties he had undertaken rendered it necessary for him to resign, the meeting adjourned till the next session.

INSTITUTION OF CIVIL ENGINEERS.

At the meeting of the Institution of Civil Engineers on December 9, 1862, Charles Hutton Gregory, Esq., Vice-President, in the chair. The discussion was upon Mr. Makinson's Paper, "On some of the Internal Disturbing Forces of Locomotive Engines."

It was argued, that the lateral motion of railway trains was not attributable so much to imperfections in the locomotive engine as to defects in the permanent way, which it was difficult to keep in perfect order, from the variations in the temperature, the changes in the weather, and other causes. The tendency of the reciprocating masses to produce oscillatory motion must be relatively less than formerly, owing to the greater weight of the present engines. It was doubted whether the re-introduction of the single cylinder engine would result in any advantage, as the difficulty of starting a train with such an engine would, under certain circumstances, be insurmountable; and the effect of having only a single central cylinder would be to raise the centre of gravity of the engine, thus creating a serious objection. The late Mr. George Stephenson had endeavoured to equalize the motion, by the adoption of a three-cylinder engine which had been in use for many years on the North-Eastern Railway. In that case there was a large cylinder in the centre, and two smaller ones at the sides; but the cost and the complication of the parts of that engine prevented its general adoption. It was, moreover, doubtful whether, even at the highest velocities, there was any apparent difference in the steadiness of that engine, as compared with others in which the revolving and the reciprocating masses were well balanced. However perfectly an engine might be balanced when it left the manufactory, after it had been running for some time, from numerous causes the springs required re-adjustment.

As regarded the disturbing forces which were said to arise from the pressure of the steam in the engine, it was contended that the unbalanced pressure upon a bearing at any time was only that due to the force driving the engine by that particular bearing. If it were possible to suppose a case of a locomotive with only one wheel, such an arrangement would no doubt tend to produce sinuous motion, with a force proportioned to the distance of that wheel from the centre of gravity of the engine. But with two wheels keyed fast upon the same shaft, of such strength as not to yield appreciably under torsion, there could be no difference of pressure (of this kind) between the two sides of the engine; and that was true wholly irrespective of the number of cylinders, or of the places where they were put. An engine capable of producing 1 ton of tractive force must distribute it over the two bearings, and there would, therefore, be ½ a ton on each bearing. Even if the engine were driven by one cylinder, it was manifest it could not put a pressure upon one side of that engine which was not equalled by that on the other side at the same moment; and that there could not possibly arise any sinuous motion from the driving pressures. Referring to the disturbances caused by the momentum of the parts, it was observed that, though the force of the parts in motion increased as the speed became higher, the times through which they acted decreased; for it could be shown, that the distance, through which these forces were capable of moving an engine, must be the same for all velocities.

As to the distance which the forces spoken of ought to move an engine, it was demonstrated that, with a locomotive the crank shaft of which was making three hundred revolutions a minute, with a length of crank pin of 1 foot, producing a velocity of 63 miles an hour, and the moving parts belonging to each cylinder of which engine weighed 500 lb., the total weight of the machine being from 27 to 28 tons, there would be an amount of motion equal to only 14-100ths of an inch. And it must be remembered, that while this would be the extent of each motion, the number of such motions, as they occurred at each revolution of the crank shaft, could not increase for a given distance travelled over, although from the greater number of revolutions per minute of a high velocity over a low velocity, there would be a greater number of revolutions in a given time.

Supposing, however, that the disturbances were as great as had been represented, then a better remedy than the single-cylinder engine would be, either the plan introduced by Mr. Bodmer in 1834, and modified by him in 1841, of having two pistons in one cylinder, both the piston-rods issuing at the same end, one being made hollow to admit of the passage of the other; or the duplex engine brought forward at the late International Exhibition by Mr. Haswell, the Engineer for the Austrian States Railway Company, who proposed to employ four cylinders—two for giving a forward, and the others an aft motion. It was stated that, in the year 1836, the late Mr. W. Weallens had designed an engine with four cylinders, similar in every respect to that last referred to.

It was suggested, that the Paper would have been more complete, if, as well as pointing out the forces tending to produce lateral motion, or oscillation, the measure of the effects of those tendencies had been calculated. Taking the forces exactly as given by the author, it was remarked that the total lateral translation, to the right or to the left, in the mass of an engine by those forces, would be in one case 1-5th of an inch, and in another 1-10th of an inch; and at a velocity of 85 miles an hour, each of those forces would act during about ¼th of a revolution; and that as there were two revolutions in one second, the diagrams represented forces acting during the ⅛th part of a second. The result of this theoretical investigation had been to show, in a visible form, a series of tendencies which certainly existed, and knowing where they existed, however slight, precautions could be taken to diminish their effect. It was evidently most important to allow sufficient play between the flanges of the engine and the rails,—that they should not fit too closely. It was considered that the estimated amount of the oscillation was so slight, that any great deviation from the established form of engine could not be recommended; certainly not the substitution of a single-cylinder engine, with all its mechanical inconveniences, for the present double-cylinder locomotive.

With regard to the effect produced by the unbalanced reciprocating parts of an engine, it was thought that the 1-5th of an inch could not be accepted as the real measure of the sinuous motion of most engines. In practice it had been noticed that, even with a good road, the lateral oscillation amounted to 2 inches, and if the road was in bad order, then it would be much more. But this did not express the evil in its true form; as it was (or might be, at any instant that the flange was in contact with the rail) a question of the amount of force exerted against the rail, tending to bend the rail, or to break the chair. As to the balancing of the reciprocating masses, direct trials were required to show the alterations necessary to be made in the positions and weights of the parts, before the best result could be arrived at. There were many objections to a single-cylinder engine, besides the difficulty of starting the train. Among these, the irregularity in the tractive power, in place of a somewhat distributed force, was alluded to, as being likely to cause a jolting action, which might give rise to accidents, from the fracture of the couplings; and it was shown that, when using full steam throughout the stroke, the maximum and minimum rotary power of the double-cylinder engine varied in each quarter of a revolution of the cranks, nearly in the proportion of 14 to 10, whilst in the single-cylinder engine the variation was as much as 20 to 0. It was suggested that the most uniform rotative power would be obtained by using two cylinders, and cutting off the steam a little before and a little after the half stroke. Further, it would be a great improvement, if locomotive-engine builders, in common with marine engineers, would use steam-jackets, both to the cylinders and their covers.

It was believed that the discrepancy between the amount of the lateral motion produced by the disturbing forces as calculated and as found in practice, arose from the circumstance, that the theory was based upon the supposition, that the wheels were without flanges. When the direction of the course of an engine at a high velocity was suddenly altered by any disturbing force, the undulation of the engine brought the flanges into violent contact with the rails, and the elasticity of the rails caused the engine to rebound, or rather glance off, against the opposite rails. When the rebound happened to be simultaneous with a disturbing force acting in the same direction, the maximum oscillation was caused; but the rebound was in some degree neutralized, when the disturbing force acted simultaneously in the opposite direction. In support of this view it was adduced, that the oscillations of an engine were not coincident with its pulsations, as they would be in the theoretical case of an engine without flanges; but that they were very irregular, sometimes extending over a period of eight or ten pulsations.

In the deductions as to the extent to which the oscillation of the engine was occasioned by the varying operations of the steam in the cylinders, the whole weight of the engine had been taken into account; whereas, it was contended, that only that part of the mass which was upon the springs ought to be considered. The motion communicated to this portion of the bulk of the engine would be in excess of the estimated results; but even then, the amount of oscillation which was known to exist would not be arrived at. With a perfect road, and an engine accurately adjusted, it was not possible to put that engine exactly straight upon the rails. Nor could any slight defects, such as the wheels being out of truth the one-hundredth part of an inch, be detected. Neither were there any means of investigating the extent to which these defects prevailed, because they might be acting either together, or in opposition to each other, and thus might aid, or retard the oscillation, or the tendency to oscillation, which the backward and forward pressure of the steam in the cylinders must occasion to the boiler and other parts connected with it.

In reply upon the discussion it was remarked, that if all oscillation was to be referred to defects in the permanent way, it might be asked, why travelling on a railway worked on the atmospheric principle was so decidedly superior, in ease and steadiness of motion, to travelling on a line worked by locomotives. It was believed it had been established in the Paper, that even if the permanent way were mathematically perfect, locomotive engines of the ordinary construction would create lateral and oscillatory movements of a grave character at high speeds, and results similar to those produced by numerous small depressions in the level of the rails. It had been maintained, that any oscillation in the engine, produced by the internal disturbing forces, would be the same at all velocities. This involved two erroneous assumptions. It had been taken for granted, that the time allowed for the oscillation varied inversely with the velocity of the engine, and that the disturbing force varied directly as the velocity. Now it had been shown, in the diagrams, that at 26 miles per hour there was a tendency in the engine to make two oscillations in each revolution of the driving wheel, whilst at 52 miles an hour there was a tendency to one oscillation only, in each revolution; so that the time allowed for an oscillation was the same, whether the train was moving at 26 or at 52 miles per hour. The pressures tending to produce oscillation were opposed by the friction of the wheel on the rail. The difference of these two pressures was the moving force producing tranverse motion; and whether this friction was assumed to be the one-fourth or only the one-tenth of the insistent load on the wheel, the moving force increased more rapidly than the velocity. Applying the same dynamical law which had been employed by several speakers, for calculating the measure of the effect of the tendencies to lateral movement of the front end of an engine while running, it was shown that, even so well-proportioned an engine as the "Great Britain," at 52 miles per hour, with a greasy state of the rails, would twice in every revolution of the driving wheel move laterally ¼ of an inch, and would strike the rail with the wheel flanges. A blow, once originated, between the flange and the rail would, from their elasticity, entail a series of blows at regular intervals of time; and should any of the series coincide in time and direction with the constantly recurring impulses to transverse movement originated by the engine, a heavier blow between the flange and the rail would follow; and this would be repeated, so that it was conceivable, that the pressures shown on the diagrams, occurring simultaneously with the rebound of the wheel from the rail, might ultimately induce a lateral pressure great enough even to drive the flange of the leading wheel up the rail, and so to cause the engine to leave the rails.

LEA'S IMPROVED CASEMENT FASTENER.

The great difficulty of keeping sashes, known as French casements, open to any desired extent, for the purpose of ventilation, has been severely felt. The present invention, which we illustrate in the accompanying engravings, and recently patented by Mr. W. Lea, of Wolverhampton, entirely overcomes the difficulty.

The invention consists in securing to the back of one flap of the hinge, by means of a pin, one end of a quadrant carried through an aperture in the flap itself; the other end of the quadrant passes through another aperture in the other flap of the hinge. At the back of the second flap, free to move on a pin, a rod or lever is fitted, which projects beyond the flap, and which is armed with a tongue or catch. Notches or holes are made in the quadrant, and on bringing down the lever so as to engage the catch into one or other of the notches or holes, the casement is retained open to the extent allowed by the particular notch or hole engaged until the catch is released.

Fig. 1 is a perspective view of a hinge constructed according to this invention and applicable for a casement opening inwards, and fig. 2 is a back view of one of the flaps showing the rod or lever which retains the quadrant in the required position; *a*, a^1, are the two flaps of the hinge, *b* is the quadrant secured by a pin to the back of the flap *a*, and passing through the aperture *c* in the flap, the other end of the quadrant passes through the aperture c_1 in the other flap a_1. At the back of the flap a^1 is fitted a rod or lever *d* free to move on the pin *e*; this lever *d* projects beyond the flap and is armed with a tongue or catch *f*. On bringing down the lever, the tongue or catch *f* engages into one or other of the notches *g* in the quadrant, and the casement is thus retained open to the extent allowed by the particular notch engaged.

Fig. 3 is a front view, and fig. 4 a top view of a hinge applicable to casements opening outwards, and fitted with a screw for engaging into holes in the quadrant *a*, a^1, are the two flaps of the hinge, and *b* the quadrant as before; *c* is a screw passing through a tapped lump *d*, and taking into holes *e*, *e*, in the quadrant. According to the hole into which the screw *c* takes, the casement is retained open to a greater or lesser extent.

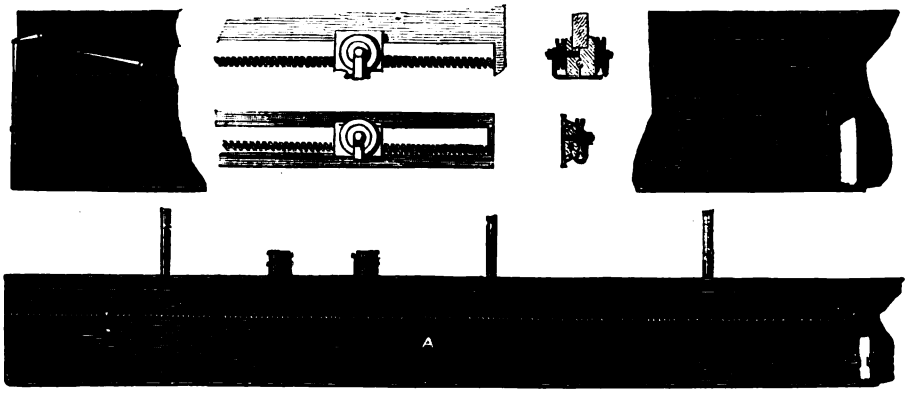
APPARATUS FOR PREVENTING THE FOULING OF IRON SHIPS.



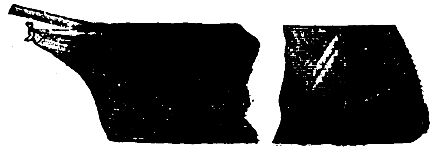
APPARATUS FOR PREVENTING THE FOULING OF IRON SHIPS.

Dr. James Gray read a Paper on this subject before a recent meeting of the Scottish Shipbuilders' Association.

After some introductory observations, Dr. Gray said: The fouling of ships' bottoms greatly retards their speed, and the attention of scientific men has been long directed to this subject. As yet, however, no plan has been suggested which fully answers the purpose designed. Fouling is chiefly caused by the adherence of sea-weed, mud, and slime, and the attachment of shell-fish; but it is the *living load* that is so difficult to remove. The young of these animals have the power of locomotion, and when they first adhere to an object they are soft and gelatinous; they harden as they mature, and become permanently attached. The species most destructive to wooden ships are the Limnoria Terebrans and Teredo Navalis; those that adhere to iron vessels are the Asteroida, Mollusca, and Cirrhopœda. In passing we may glance at the means which have been tried, although it is evident the wrong weapons have been employed against the enemy.

In early times, when vessels were small, preparations of sulphur, mixed with suet, rosin, or pitch, were used to prevent the ravages of Limnoria Terebrans and Teredo Navalis in wooden ships; and, later, copper plates were introduced on the sides of ships. But it was found that, although they protected the vessel from the ship-worm, Barnacles and various Mollusca adhered to the copper, and retarded the progress of the vessel. Zinc nails were then inserted in the plates, and a galvanic battery was formed on the ship's side; oxidation of the copper took place, and, so long as the oxide was bare, it acted as a poison on the ova of the Mollusca. When, however, the oxide got covered with sea-grass, slime, or mud, the animals adhered to this coating, and the vessel was again clogged. The same process could not so well be tried on iron vessels, as the galvanic current would injure both iron and copper, and it was recommended to try Muntz's metal, with a non-conducting agent between the iron and copper. This mode, although expensive and attended with difficulties, was adopted, but with very little effect; indeed, it would seem as if the Mollusca community regarded with supreme contempt the gigantic measures taken to dislodge them, and holding their property rights by virtue of *possession*, their security remained undisturbed. These creatures, moreover, seem quite as strong in home attachment as ourselves, and apparently have as little inclination to *flit*, when comfortably settled down, as have human families. The latest, and most expensive, recommendation is the electro-typing process. Mr. Wallen claims as the merit of his invention, that he can precipitate a pure metal, or combination of metals upon iron of any uneven form with a perfectly even and bright surface, but as barnacles adhere to the smoothest surface, even to glass, the object sought will not be obtained, and there can be no doubt that the sheathing and coating of vessels with costly metals is merely to *garnish* the habitation of the enemy—a useless extravagance; for if the copper is not oxidized, the ova of the shell-fish will adhere; if it become oxidized, the thin layer will soon corrode, and the expensive process of electro-typing will require to be repeated.

A great variety of paints and compositions are in use for anti-fouling purposes, but the objections to these are, that they can be plastered over with seaweed, mud, and slime, and the poison which enters the paints is prevented from acting on the ova of the Mollusca. The compositions which are effective in destroying the animals have an injurious effect on the iron. Arsenious acid, for instance, contains three atoms of oxygen, part of which being given to the iron, ultimately destroys the plates. The same effect is produced by common red lead paints, which also contain three atoms of oxygen, the red lead parts with its oxygen, and the iron is oxidized. I would recommend that an anti-oxidizing paint be prepared for ships' bottoms, and this part of the work of a vessel should be more carefully gone over. Frequently before the paint is sufficiently dry the ship is launched. Hurried coatings of paint may effect a saving at the time, but it is in the end being penny wise and pound foolish; for if the paint has not time to harden before the ship is sent into the water, and a thick coating laid on, the water passes through the pores of the paint, and the iron becomes oxidized. An outer coating may seem perfect, and yet the plates be so oxidized that a foot can be thrust through the ship's side after a few voyeges. An anti-oxidizing paint (such as I showed in the late International Exhibition), carefully applied, and allowed to harden between each coating, would amply repay in the end the loss of time in the work.



My attention being directed to the fouling of ships' bottoms, I was led to experiment with different coatings on iron plates. These were deposited in Largs Bay for some months; but I found, although successful in preventing the ova of shell-fish from adhering, the coating required to be renewed, and the surface of the plates cleaned. On careful consideration I became convinced that it was only by mechanical means the living impediments could be removed, and having decided this in my own mind, I invented the "Apparatus" now before your notice.

This invention has for its object the cleaning of ships' bottoms in an effectual manner, either while the vessel is sailing or in port; and it aims at *preventing* fouling, or accumulation of shell-fish or sea-weed, by providing means for continually removing adhering matter when beginning to attach itself, and when it is most easily removed. It is applicable both to wooden and iron vessels.

The apparatus is simple, and can be worked by manual or steam power in the following manner:—A brush, or scraper, is made to pass from stem to stern, or from keel to water's edge, daily, or as often as required; it is worked by means of guides at both stem and stern as shewn in which a block is raised and lowered by a screw; a pulley is attached to the block for the brush rope passing under; at the stern is placed a double-barrelled and double-brake winch; the brush rope is fastened to one of the barrels, and passes down the stern along one side of the ship's bottom to the stem, as shewn in the cuts, and along the other side of the ship's bottom and up the stern, where it is attached to the second barrel of the winch; while winding with one barrel, the rope is kept taut by the brake on the other barrel. The guides, if bolted to a screw steamer, may be passed down the stern as far as the swell for the screw shaft; in an armour-plated vessel, the guides can be placed in the plates. When it is not convenient to have a screw, the block for the brush rope can be raised or depressed by a rope or chain fixed to the top and bottom of each block. The chain or rope attached to the bottom of the moveable blocks passes in a groove along the keel, protected by a tube or lid; the rope attached to the top is wound round a small winch brake at both stem and stern.

Another mode of application is by an endless chain, or rope, passing under a pulley attached to the bottom of the vessel, and round a small winch barrel on the deck; the block for the brush rope, with pulley attached, is fastened to this chain, and raised or lowered by winding round the small winch. In this way the brush ropes are wound round winches at bow and stern, each side having a separate rope for itself. The brush may be made of whalebone, galvanized wire, or vulcanised india rubber. If required, a knife or scraper can be fastened to the brush to secure the removal of every impediments. In long vessels two brushes can be used, in which case they will only have to travel half-way. For ships of war I would recommend the screw; merchant vessels may be worked by the endless rope; for yachts, and smaller craft the chain along the keel.

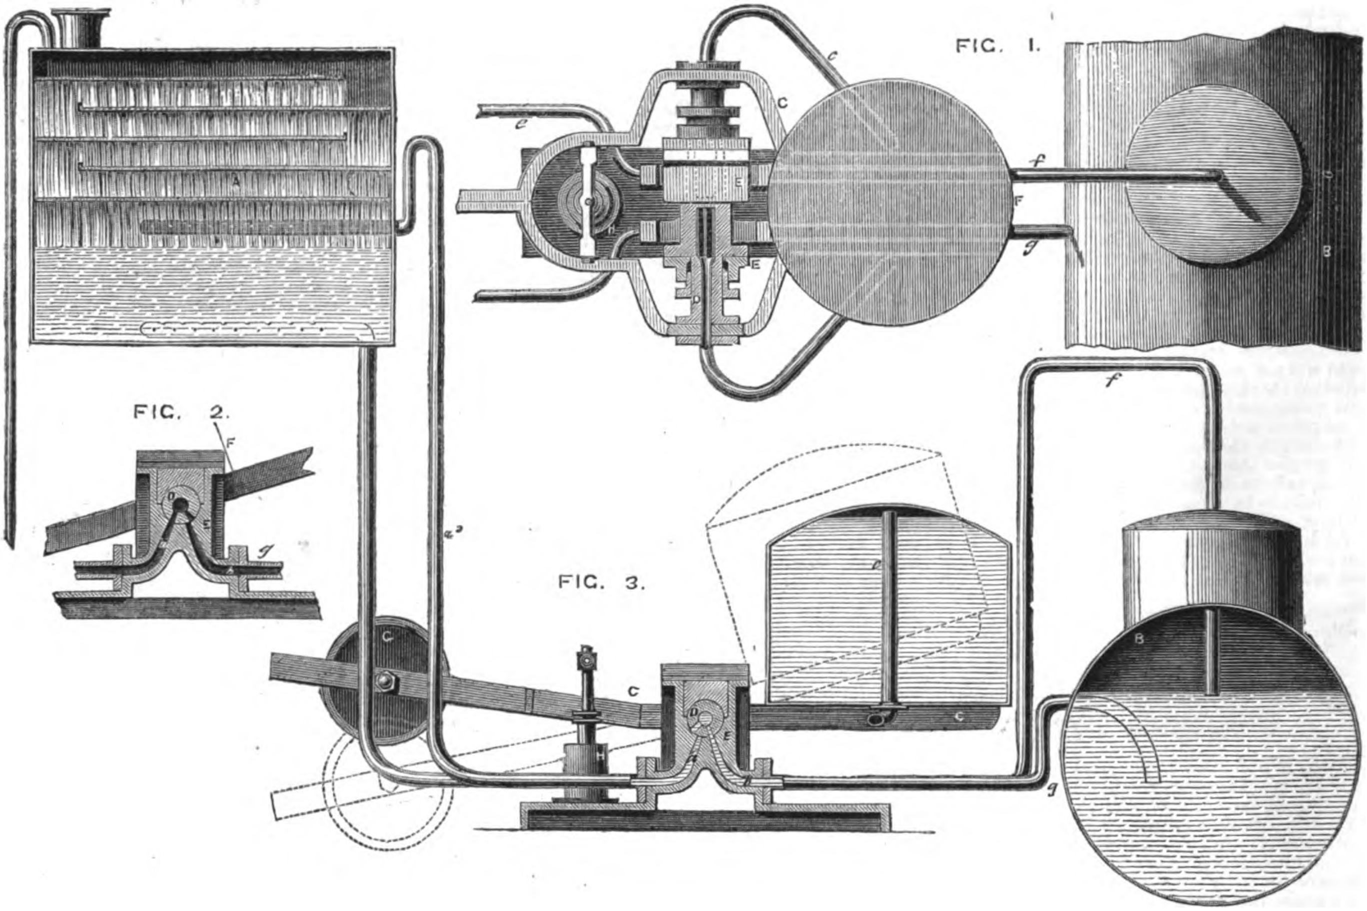
It may be objected that frequent brushing will wear the paint and damage the ship's side; but this will not be the case if vessels are properly coated with anti-oxidizing paint, as suggested. This invention would save the expense of dry-docking ships, and prevent time being lost in running them into the mouths of rivers in warm climates for the purpose of cleaning; and an important advantage would be secured in increased rate of speed—valuable cargoes could be got into the market at top prices, and to ships of war the difference of a clean bottom would materially assist a successful enterprize. Speedy voyages would curtail expenses in seamen's wages, food, fuel, insurance, and otherwise effect a vast saving.

In closing, I would impress the fact on your minds, that it is only when the living impedementa are in an ova state that they can be removed, and when the animal is soft and gelatinous, in the infancy of development, and this can only be effected successfully by a mechanical appliance.

FOGS AND FOG SIGNALS.

On the 13th ult. a lecture on this subject was given before the Royal Institution by Dr. Gladstone:—A fog, the lecturer said, was a cloud on the surface of the earth, and, quoting Dr. Tyndall's definition of a cloud as the visible capital of a pillar of invisible vapour, added that a fog was the capital without the pillar. The constitution of a fog was the same as that of an ordinary cloud: it was composed of water in the form of minute globules; there was no ground for believing that the water existed in the form of vesicles. A simple fog had the same appearance as a cloud, and the peculiar colour of a London fog was due to smoke. The lecturer then dwelt on the importance of fog signals to mariners, and showed the obstruction fogs offered to the passage of light, explaining that a simple mist offered great obstruction. He remarked that the character of the light exhibited on lighthouses was a matter of great importance, and showed that a fog entirely cut off the blue end of the spectrum, relating that the electric light displayed on the Monument on the evening of Tuesday, the 10th, was seen through the fog at Hampstead as a red light. Red light had been found to penetrate farthest, and Dr. Gladstone showed the effects of the coloured glasses used in the French and English lighthouses, the French being composed of red and orange, and the English of red only, the latter being visible at the greatest distance. The lecturer then said that for practical purposes it was necessary to distinguish between a mist and a fog, but this was not an easy matter. The same thing had a very different appearance to different observers. Landsmen in general had very loose notions about a fog, but a sailor's ideas on the subject were more definite. The lecturer showed by a reference to the reports of several lighthouse keepers on one corner of Scotland that what was evidently the same fog was variously reported as fog or as simple mist. In order to get uniformity in these reports, Mr. Cunningham had proposed to erect a pole, painted vermilion, as a test object, and suggested that everything which rendered this invisible at a hundred yards should be considered a fog. This test had been accepted by Mr. Glaisher, and may be generally received. The returns from various lighthouses round our coasts showed that fogs were sometimes of very small, and at others of very large extent. In London they were generally local; but a comparison of the returns of lighthouse keepers had shown the lecturer that some extended over a large area. There was one on April 14, 1861, which enveloped nearly the whole coast of Ireland, and was also seen in Wales, Scotland, and on one point of Cornwall. On April 1 of the same year it was foggy over nearly all Europe. Fogs had been found to be more common at one time of the year than another. November was considered the foggiest month in London; but in the South they prevailed most in January and June. The east of Scotland was in general free from fog in January, but had many in September, May, and June. In Ireland there was seldom any fog in February. Some years, too, were remarkable for fogs. England, the lecturer said, did not deserve its reputation for fogginess, statistics proving that fogs were not more frequent here than in other countries. The sea was much more uniformly covered with fog than the land; and it was found on our coasts that high headlands with a south-west aspect were peculiarly liable to fog, which was explained by the fact of a south-west wind coming loaded with moisture from the Atlantic.

The lecturer then entered upon the subject of fog signals, and showed that, light failing, it was necessary to have recourse to sound. Many means of producing sound had been used—bells alone, and bells with mirrors behind them (as at Boulogne) to collect and send forward the sound. Gongs had been used on lightships, guns were also employed, and steam-whistles, which last were highly spoken of. Sea-birds had been encouraged on the Skerries, and were believed to have been of some use, until some rats escaped from a shipwrecked vessel and began to devour them. A cat was introduced to remedy this, but it was found, unfortunately, that she preferred birds to rats. The objection to the use of sound was that it did not indicate the direction of the danger, but still it had at times been useful to steerers, and Dr. Gladstone related one or two instances in which vessels had been safely steered, the steerer being guided by sound and the constant use of the lead. Another objection was that one sound was easily confounded with another sound. Bells were rung for many purposes, guns were used as signals of distress, steam-whistles were always going; but still it might be found possible to agree on some plan to regulate a system of sounds. One more objection was that a breeze interfered with the passage of sound. It was true that in a dense fog there was generally a calm; but then came the most serious objection of all—that fog affected the transmission of sound, not so much as of light, but still to an appreciable extent. The composition of a fog, too, had a great influence on sound. Perfectly damp air was a much better conductor than a dry atmosphere mixed with some fog. As the use of sound, however, could not be discarded, it was necessary to find out the quality of the sound which was able to travel farthest, and fall back on experiments to ascertain this. Many had already been made, and more were in progress. Horns, trumpets, whistles, and whistles combined with a rattle, guns on a level and guns on a height, had all been experimented on, as well as the influence of pitch, and the repetition of discordant rather than concordant sounds. The influence of the background had also been examined. When on this part of the subject, the lecturer exhibited a small model of Professor Holmes' trumpet, BRIERE'S PATENT APPARATUS FOR FEEDING STEAM BOILERS.



which was sounded, and which gave the audience a satisfactory idea of the power of the instrument. The transmission of sound through water was then considered, and, as this would be totally unaffected by waves or fog, Dr. Gladstone deemed this the most fruitful line of investigation.

BRIERE'S PATENT APPARATUS FOR FEEDING STEAM BOILERS.

A patent has been obtained in this country by M. Brière, of Brussels, for a continuous self-acting condenser and boiler-feeding apparatus, which the patentee describes as follows:—

Fig. 1 of the annexed engravings shows a partial plan view, and fig. 2 a longitudinal section of the feed water apparatus, the same being interposed between the boiler to be supplied and the tank forming the source of supply. A is the supply tank, and B the steam boiler; C is a rocking frame mounted upon and keyed to a rock-shaft D, which is made hollow through the greater portion of its length and furnished with lateral openings. This shaft, therefore, besides carrying the frame C, forms also a pair of rocking cylindrical valves. The valves are each furnished with two lateral passages and they are mounted in valve boxes E, E, which are formed with two diverging passages *a*, *b*. The passage *a* of the valve box E communicates with a water supply pipe leading from the water tank A, and the passage *b* communicates with a water supply pipe leading to the boiler B. A similar arrangement is adopted with respect to the valve box, one passage being connected to a steam pipe leading to the tank, and the other *b* to a steam pipe *f* leading to the boiler. The rock-shaft D is coupled at its extremities with pipes *c*, *c*, which lead into a closed or steam-tight chamber F (which I call a condenser), mounted on one end of the rocking frame C, and above the water level of the boiler B. The other end of this frame car- an adjustable weight G, which is intended to rbalance the weight of the condenser and its contents at a certain period of the action of the apparatus, and thereby rock the frame into the dotted position, for the purpose of shifting the valves and stopping or diverting the passage of the water and steam through the apparatus for the purpose to be presently more particularly explained. The pipes *c*, *c*, enter the chamber or condenser F at the bottom, and one pipe projects to near the upper end thereof, while the other stops short at or near the bottom. The object of these pipes *c*, *c*, is to supply the condenser alternately with water and steam. As, therefore, the water accumulates in the condenser, the weight G will be overbalanced; and as the water is discharged therefrom, the condenser will rise. When the water in the boiler falls below the proper water level, steam is supplied to the condenser from the boiler B by the steam pipe *f*, which dips down from the crown of the boiler to a point a little below the water line. The pipe being coupled, as already explained with the valve-box, conveys steam to the interior of the valve contained in that box (the valve being at the time in the position shown in section in fig. 2). As the pressure of the steam in the boiler and condenser is equalized (the valve being at this moment in the position shown at fig. 2), the water will flow down from the condenser by the pipe *c* to the valve, thence down the passage *b* to the pipe *g*, and by that pipe into the boiler. The condenser being lightened by the discharge of water therefrom, the counterweight G will come into action, and through the rocking frame C shift the valves to the position shown at fig. 3, thereby opening a passage for the escape of the uncondensed steam (if any) from the condenser, and by the valve opening a passage for the supply of water from the tank. Water descending by its pipe will enter the passage *a*, and passing through the valve in the valve-box will flow by the pipe *c* into the condenser. The chamber F being now filled, will fall and the valves will be shifted again to the position shown at fig. 2, thereby allowing a fresh supply of water to descend from the condenser or chamber F into the boiler, and at the same time opening a way for the steam to escape therefrom as before noticed. This escape steam, after having performed its office in the chamber F, may, at the next shift of the valves, be conducted from the chamber F by the pipe *e* into the water supply tank when the supply water is required to be heated, or it may be discharged into the atmosphere. To facilitate the heating of the feed water, the water may be discharged from its primary source on to trays in the tank and fall in thin streams from one to the other, as shown at fig. 2, the steam let into the tank passing up and mingling therewith. For the purpose of acting as a check to the vibration of the rocking frame C, it may be convenient to provide a brake apparatus as shown at H, consisting of a water cylinder and loose piston, the latter being connected by a cross-head to the framing. The play of the piston in this cylinder will offer a sufficient resistance to the movements of the rocking frame to prevent a too sudden or beating action.

CLEMENTS, LLEWELLIN, AND JAMES'S SELF-ACTING LUBRICATOR FOR STEAM ENGINES.

The annexed engravings illustrate an invention recently patented by Messrs. Clements, Llewellin, and James, of Bristol, for a self-acting lubricator for steam engines.

The invention relates to a novel apparatus which, when adapted to the steam supply pipe of an engine, will supply a regulated quantity of the lubricating material to the inside of the valve box and cylinder, and other working parts of the engine.

Fig. 1 is a front elevation, and fig. 2 a side elevation, of the apparatus complete and ready to be adapted to a steam supply pipe; fig. 3 is a top or plan view of the same, and fig. 4 a plan of the under side.

CLEMENTS, LLEWELLIN, AND JAMES'S SELF-ACTING LUBRICATOR FOR STEAM ENGINES.

FIG. 2.

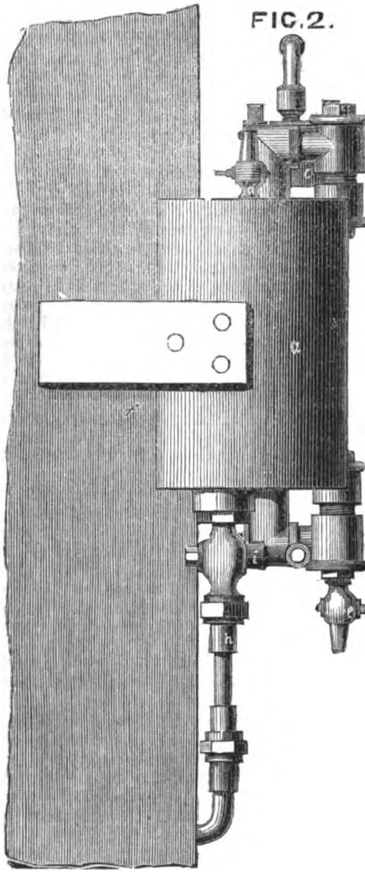


FIG. 1.

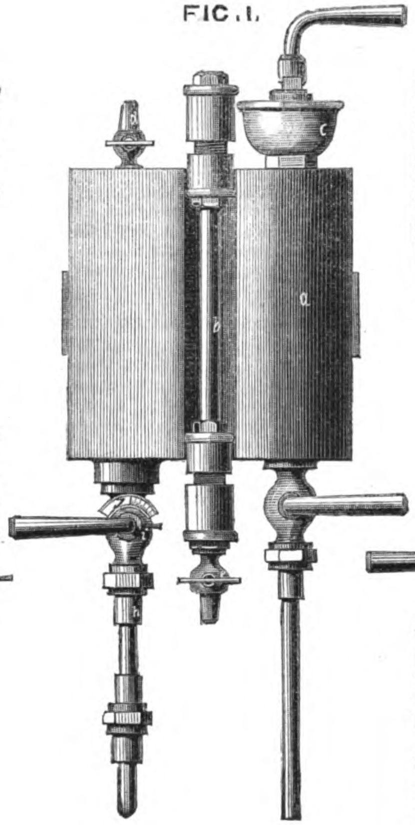

FIG. 3.

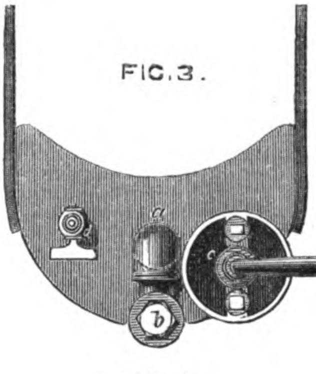

FIG. 4.

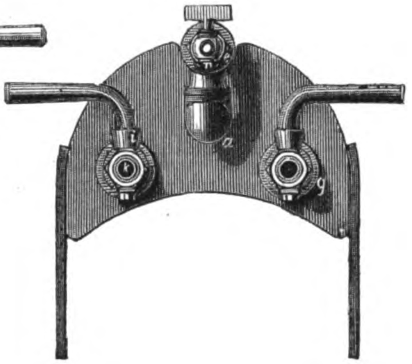


The apparatus consists of a steam-tight vessel *a*, for holding oil, tallow, or other lubricating material, and which is provided with a glass tube *b* for showing the height of the lubricating liquid in the vessel *a*. On the top of the vessel is placed in a funnel *c*, provided with a valve for charging the vessel *a*; and in order to facilitate this operation, an air cock *d* is fixed in the top of the vessel *a*, for the purpose of allowing the air contained therein to escape when the lubricating material is supplied thereto. A similar cock *e* is also placed at the bottom of the vessel, to admit of the condensed steam or foul tallow being discharged when required.

The apparatus is attached to the steam supply pipe *f*, by means of any suitable connection, provided with a cock or valve *g*, for regulating the admission of steam into the vessel *a*, through a pipe carried above the surface of the tallow or lubricating material, as shown by dots in fig. 1. There is also another pipe *h*, to conduct the oil, tallow, or other lubricating substance to the slide valve, the cylinder, piston, air pump, and other internal parts of the engine. The pipe *h* is provided with a cock *i*, and a divided sector index plate *j*. The handle of the cock *i* is provided with an index or pointer i^1, which when the cock is turned to admit the lubricating material from the vessel *a*, to pass into the tube *h*, will indicate the exact extent to which the cock is open; by this, after a little experience, the engine man or attendant will be enabled to regulate the supply of lubricating material with great accuracy.

It will be understood that when the regulated supply of the lubricating substance is allowed to pass the cock *i* into the tube *h*, it will be carried forward into the engine, by the current of steam that is admitted to and made to pass through the vessel *a*, and into the pipe *h*, with the lubricating material, which latter will therefore be distributed over the whole of the parts requiring lubrication.

By means of the above apparatus, it is said that not only can all the working parts be more thoroughly and efficiently lubricated than heretofore, but a saving of one half the tallow or lubricating material usually consumed will be effected.

The apparatus is simple in its arrangement, and is capable of distributing the lubricating substance over the whole of the internal surfaces of the engine from one source, the supply being regulated to the greatest nicety by means of the cock *i*, as above explained.

EXPERIMENTS AT SHOEBURYNESS.

On Friday last the members of the Ordnance Select Committee and the Ironplate Committee, with several officers of the Artillery and Engineers, made some novel gunnery experiments at Shoeburyness both with cannon and forms of projectiles. The first was made by the Ordnance Committee entirely, and consisted of trials to ascertain how far a method now rather in favour among French artillerists—by which a series of holes, about an inch in diameter, are bored through the substance of the cannon near its muzzle, in order, by permitting a quick escape of gas, to diminish its recoil—affects the service of the piece as to range and accuracy. The experiments were made with two brass nine-pounder ordinary smooth-bore field-pieces, which were loaded with the usual service charges and spherical shot. Five rounds were fired from each gun in succession, the recoil of both being carefully measured after each discharge. They were then shifted, so that each occupied the platform which had been used by the other, when again more rounds were fired. The minute official results of the experiment are not likely to be made out for some days, but the general merits of the performances of each gun could be seen at a glance, and were exactly what were anticipated before a shot was fired. The recoil of the ordinary guns was, in round numbers, just twice as great as that which had the holes bored round the muzzle, while the range and accuracy of the latter were scarcely more than half as good as that of the common piece. The lateral escape of gas and flame through the side holes of the French gun, if we may so call it, was very great indeed, so much so as to prove at once that, even if the gun otherwise possessed the most transcendent merits, it could never be used either on shipboard, in casemates, or even at embrasures. In the open air on Friday the trigger had to be pulled by a lanyard nearly 20 yards long. One half of the force of the explosion evidently escaped through the side holes before the force of the powder was expended on the shot, and virtually therefore the barrel of the gun is shortened by as much of its length as is thus perforated. As a general rule, the recoil of the gun is always in exact proportion to the force it exerts in propelling the shot, and anything which takes off from this recoil, by allowing the gas generated by the explosion to escape before it has done its work, just diminishes by so much the range, and, therefore, the accuracy of its fire. The results obtained with this curiously bored gun on Friday were enough apparently to satisfy the Ordnance Committee that it would be a waste of time to continue the experiments further.

Some experiments were then made with the Armstrong 110-pounder service-gun, loaded with steel shot, against a box target faced with 4½-inch plates, and lined inside with teak and an iron skin like the "Warrior." The only interest of this experiment was to test the penetrative power of the projectiles, one of which was prepared by the Ordnance Committee, weighing 65lb. and fired with a 16lb. charge of powder. The immense superiority of this projectile over the cast and wrought iron shot, which, as the standards or units of penetration, were fired at the target before, was at once apparent. Its indentation was nearly 50 per cent. deeper than either the wrought or cast iron missiles. The next shots tried were those of a peculiar kind of steel made by Messrs. Makin and Sons, of Sheffield. Friday was the third time that steel shots supplied by this firm have been tried at Shoeburyness, and always with the same result—that their metal, both for toughness and hardness, is superior to any other kind that has yet been experimented upon. A conical-headed shot of this kind, of which the cone was small and sharp, with a very full shoulder, weighing 65lb. and propelled by only 14lb. of powder, smashed its cone completely through the plate, damaging the backing and breaking a rib behind—the greatest result that has ever been obtained with so light a shot and so small a charge. It was evident that only the very full form of the shoulder beneath the cone (part of which was sheared off) prevented the whole going completely through the target. A second shot of the same kind, the same weight, and fired with the same charge, struck the upper plate of the target on an uninjured part, and about 12 in. from its edge. It completely smashed away a piece about 15 in. deep by 18 or 20 wide, splintering and ripping up the backing behind. One piece of the plate, of considerable weight, was carried far behind the target where it fell with the shot itself. An examination of the latter showed a part of the cone broken off, but in other respects it was little injured, though the injury to the target was very formidable, in spite of the hard, rather than tough, character of its metal. The trial seemed to show that, to pierce the plates, almost as much depends upon the metal of the projectile as upon either the gun or charge of powder which fires it. Certainly, the result seemed quite to upset the notion that a flat-headed shot is essentially necessary to punch armour plates, and, on the other hand, to strengthen the belief that the best form for this purpose may, after all, and with proper metal, be found to be the conical form adopted by Sir William Armstrong. There was only one opinion expressed as to the quality of the metal supplied by Messrs. Makin—it was, as we have said, the best that has yet been tried.

As it seems probable, from the remarks made in the House of Commons the other night, that some members intend to honour future experiments with their presence, we would, as a preliminary step, earnestly recommend them to take a liberal view of the Shoeburyness estimates, in order that some really stout splinter-proofs may be erected, from which they may see the trials with something like safety. Without some such additional safeguard, even all the care and precautions taken by Colonel Taylor cannot long avert an accident. On Friday the officers engaged and all the members of the committee had very narrow escapes from two large fragments of steel splinters which came through the splinter-proof and passed over the heads of those crowded in it, fortunately without touching any one. All the splinter-proofs are more or less rough, temporary erections, made of any strong materials that are nearest to hand. And, indeed, in all its appliances for shifting guns, &c., there is an evident want of proper means to the end, which is not what one expects to meet in a practice ground of such national importance as Shoeburyness has now become. This want of a proper plant doubles the labours of a most zealous staff of officers, who, without such additional duties, are already almost overworked.—*Times*.

TO CORRESPONDENTS.

The Mechanics' Magazine is sent post-free to subscribers of £1 1s. 8d. yearly, or 10s. 10d. half-yearly, payable in advance. Post orders made payable to Mr. R. A. Brooman, of 166, Fleet-street, E.C.

Advertisements are inserted in the Mechanics' Magazine at the rate of 6d. per line, or 5½d per line for 6 insertions, 5d. per line for 13 insertions, 4½d. for 26 insertions, and 4d. a line for 52 insertions. Each line consists of about 10 words. Woodcuts are charged at the same rate as type. Special arrangements made for large advertisments.

To insure insertion in the following number, advertisements should reach the office not later than 5 o'clock on Thursday evening.

Correspondents who wish their manuscripts to be returned are requested to state this.

We beg our correspondents to choose initials, rather than general signatures such as "Constant Subscriber," or "Reader," &c.

Received.—J. H.

To Makers of Ice-making Machines, and of Apparatus for testing the Lubricating Qualities of different Oils.—A correspondent inquires the names of makers of the above apparatus. Any communications sent shall be forwarded to him.

T. K. (Canterbury.)—We would suggest to you, as a preparation before beginning a course of experiments in the *perpetuum mobile* line, to try to lift yourself up in a basket. After achieving that feat, you can then begin to make your "eternally moving" wheel. Perhaps, before attempting the basket experiment, it might be best to read attentively a work on Mechanical Science?

L. S.—The sole manufacturers of Giffard's Injector are Messrs. Sharp, Stewart, and Co., of the Atlas Works, Manchester. The inventor, Monsieur Henri J. Giffard, may be addressed "Aux soins de M. Fland, constructeur, Rue Jean Goujon, Paris."

S. P. T. (Manchester.)—Write to the Admiralty, stating age, qualifications, and antecedents.

James B. (London.)—We are naturally sorry to reject the communication of a valued correspondent, but on reading your article, we find that it is scarcely suited for our paper.

W. A., Civil Engineer (Milford.)—Your plan seems suitable and original, but in the pressure of engineering matter we are obliged to confine ourselves to subjects that are more specially in our line.

T. P. T. (Eliot Vale, Blackheath.)—The reason that "*we do not hold ourselves responsible for the opinions of our correspondents*," is not to escape the law of libel, but rather that we look upon the columns we devote to the letters of our correspondents as an arena for the *free* discussion of scientific subjects. Any responsibility we might assume would, of course, interfere with this complete freedom.

J. C. (Ball's-pond).—We cannot insert your last communication: it requires more condensation and better caligraphy. We rather differ from you as to the non-patentability of so-called "frivolous" or small inventions. We could, if space allowed, adduce many arguments to support our views; but, in any case, where would you draw the line of demarcation?

Correspondence.

[*We do not hold ourselves responsible for the opinions of our correspondents.*]

◆

THE SPHERE.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

Sir,—As among the Mechanics of the United Kingdom there is known to exist a lively interest not only in the practical results of geometry but in the clearness of the reasoning by which they are arrived at, the following from an old correspondent may not be unacceptable.

"On the Generation of the Straight Line and Plane, as deducible from Plato's Property of the Sphere." By Lieut.-General T. Perronet Thompson, F.R.S.

In the *Timæus* and two places in the *De Anima Mundi*, Plato calls the sphere "of all figures the most perfect," because it is "the only figure capable of both at rest and in motion fitting in the same place without either quitting it or taking up new ground; in consequence of all the points in its surface being equidistant from a point in the middle." Which is what is intended by the modern expression of "being without motion in fixed space."

This property appears applicable to the relief of some discrepancies in the outset of geometry, evidences of which exist in the five or six different descriptions of a straight line found among ancient and modern geometers.

That two spheres, equal or unequal, touch only in a point, is demonstrable with the help of the Platonic property. For, if they are supposed to touch in anything which has parts or magnitude, as for instance an area, then by turning each sphere severally about its centre, two portions of their surfaces which at one time coincided throughout, may be made at another time to coincide in some of the same identical parts, and in others be separate; which is impossible if the bodies have undergone no change of form. And the same sort of proof is applicable to a supposed contact in a line of any kind, even though self-rejoining and uniform. Also, the contact cannot be in insulated points more than one; for if the touching spheres were formed into one body, as would be done by the application of a cement to the interstices, this compound body could be turned about the two centres of the spheres, the centres remaining at rest; because the two centres can be applied to the same points in fixed space, under any number of different positions of the rest of the body. And because they are the centres of the spheres respectively, each sphere will be without motion in fixed space, and the whole compound body be so too. Whence, if on turning abouut the two centres one insulated point of contact remained at rest, any other supposed insulated point of contact must change place by moving round it; which is impossible if the whole compound body and every part of it is to be without motion in fixed space.

After this, let two spheres, equal or unequal, touch and be turned as one body about the two centres, whereupon the point of contact will remain at rest. And if one sphere be made larger and the other smaller, the centres occupying the same places as before, and the contact being maintained, the new point of contact will equally remain at rest; and the same for any number. Hence, if the alteration in the magnitudes is made to be continuous each way, the point of contact will describe a line from one centre to the other, every point in which on the line's being turned about its two extremities will be without change of place. *The line shown to be capable of this property* is called a Straight Line. And two such lines cannot inclose a space; for if one of them was turned about the points of junction without change of place, the other could not, but must be moved round it. And on similar principles may be shown that two straight lines cannot have a common segment, and that the straight line is the shortest.

An extension of the same methods will show, that if the surfaces of two equal spheres cut each other, their intersection is one line without breadth. Let then two equal spheres touch, and about the same centres describe two larger spheres equal to each other. Join the point of contact of the smaller spheres, and any point in the intersection of the surfaces of the larger, by a straight line of unlimited length. Make the whole turn about the two centres which remain at rest, and this straight line shall describe a surface having the property that the straight line between any two points in it, lies wholly in that surface.

For, in consequence of visible equalities and the Platonic property, the whole system may be turned about the two centres without change of place in the spherical surfaces or their intersection. And if the centres are interchanged (or one set of spheres put in the place of the other) and the system again turned about them, there will still be no change of place of any of the surfaces, nor in the revolving straight line when it passes through the same point in fixed space in the intersection of the spheres. Which is the same as to say the two surfaces described by the revolving straight line before and after the interchanging of the centres will be capable of mutual application and coincidence in all their parts with inversion, and be one surface. Follows from which, that any point in this surface is equidistant from each of the two centres, for the two distances can be applied to one another; and the point would consequently be in the intersection of the two equal spheres which should be described about the centres with that distance. In the intersection then of two of the larger equal spheres, join any two points, and the straight line or chord between them shall lie wholly in this surface. For, if the two extremities of the chord were made the centres of two spheres equal to the previously intersecting ones, the two original centres would be found in the intersection of these new spheres, by reason of the equality of the distance from their centres to their circumferences; and, consequently, if the whole system were turned about the two extremities of the chord which remain at rest, one of the original centres might be applied to the place previously occupied by the other. And because the chord and every point in it are during this operation without change of place, the straight line drawn from any point in the chord to one of the original centres, would be found applied to the straight line drawn from it to the other; therefore they are equal. Whence, such point in the chord would be in the surface described by the revolving straight line, and no where else; for if it were otherwise, there would be two different intersections of pairs of spheres, all equal and about the same centres; which cannot be, for the intersection will be one and the same. In like manner, every other point in the chord may be shown to be in the surface; therefore the chord lies wholly in the surface. And because through any two points in so much of the surface as is within the intersection of the spheres, a chord may be made to pass, the straight line joining any two such points lies wholly in the surface. But if one or each of the points is outside the intersection of the spheres, it may be included by enlarging the intersecting spheres, and so there may be proved as before. The surface shown to be capable of this property is called a Plane Surface.

It may not be necessary to begin by laying all this before the little boys, but grown geometricians may feel grateful to Plato for clearing the way to knowing there can exist things with the properties ascribed; the best way of doing which is to know how on a pinch they might be made.

I am yours, &c.,
T. Perronet Thompson.
Eliot Vale, Blackheath, March 27, 1863.

IRON WALLS AND THEIR ARMAMENT.

WOOD BACKING.

Sir,—It is a pleasure to encounter so rational and honest an opponent as your correspondent "Iron." He takes up the defence of wood, as a backing to armour plates, with apparently so much reason that he would almost make me question the soundness of my conviction, if it were not confirmed by the incidents of target experiments recurring from time to time. I am more convinced than ever, that wood backing is a blunder—that it is, in fact, the main cause of the destruction of armour plates under the fire of artillery.

The argument I have to hold with the writer, who signs "Iron," is of a different character from that raised by other opponents. I have not to go back to the first elements of iron ship building, to convert wooden bigots from the false to the true faith. "Iron" believes that for strength and rigidity of structure, for durability, for displacement with proportionately less weight, and above all for the construction of large ships, iron is incomparably superior to wood. When the Controller of the Navy and the Lords of the Admiralty recant their errors, as they have done before Parliament assembled, we may hope that the worship of wood, as a material for building ships, will soon not have a follower left.

"Wood as backing" is a question distinct from "wood as a material for ships;" and whatever my individual opinion may be, I admit it is open to controversy. Your correspondent advances the premisses fairly. He claims that a bed of wood under a plate performs two functions: 1st, it absorbs the blow by speading the force of the projectile over a large surface; 2nd, it protects the iron hull from the impact "of the bulge at the back of the plate which forms in the rear of the 'locus' of impact." These precisely are the two points to be considered. On the first, I answer that a hard and rigid bed, if it be strong enough to resist the crushing force, will more effectually absorb the blow and, under the same condition, will prevent buckling. Of this fact "Iron" is fully cognizant; for in maintaining that "rigid ribs at some distance apart" would increase the tendency to buckle, in which he is quite right, he virtually admits that rigid ribs at short distances apart will prevent buckling. That is my opinion; and in answer to the reproach that has often been cast upon me, that I oppose the plans of others and propose none of my own, I am *now prepared to avow my belief that narrow iron cells, less in width than the diameter of the projectile, will form an efficient backing to armour plates*. To prevent vibration, and afford a fair bearing to every part of the back of the plate, I propose that these cells be filled with wood with the grain end on, or with some other tough material, which some experiments at Shoeburyness lead me to believe will be found in millboard or "papier maché." Again, "Iron" is right in seeking to guard against the tendency of the bulge to fracture the skin or the frames which support it, if no backing be interposed between the iron hull and the armour plates. This opinion is incontrovertible, but its truth does not prove that wood is the proper material to be so interposed. On the contrary, I contend it is a bad material, because its want of density and hardness, as compared with iron, is so great, that it offers no resistance to the bulge, which, being unresisted, its formation, at the moment of impact, puts the particles of wood in motion and transmits through them the projectile force to the ship's frame. Now, if a material as hard as iron—if iron itself form the backing and bed to the plate—provided the support to that backing be not crushed in, there will be *no bulge at all;* and that is the result which, I believe, an iron cellular backing would produce. I shall not dilate on this point; it can only be determined by experiments.

But I say, "Stop the bulge and you stop the mischief." That this can be done, I have seen. In my earlier letters I referred to a trial of rigid backing at Shoeburyness. A 2½ in. plate on a backing of cast-iron blocks, being fired at by a 40-pounder, which easily penetrated that thickness on a wood backing, received only a slight indentation on the face, and had no bulge at the back. A 100-pounder Armstrong, which would have smashed the plate if backed with wood, made an indentation of only half an inch in depth, and again caused no bulge to be formed. To conclude, and repeating what I have written twenty times, wood, by yielding at the point of impact, causes the ends of a plate to buckle. This throws the strain upon the bolts and tears them away, which is the worst disaster of all; for, deprived of its fastenings, the plate falls bodily off. In the last experiments, Messrs. Brown and Co.'s 7½ in. plate was doubled up by two heavy shots striking it at the centre, which was crushed 3 or 4 in. into the wood, whilst the ends were separated from the wood about the same distance. Several bolts were visibly broken; others, no doubt, will be found cracked in two inside the wood, when the target is taken to pieces, as was the case with many bolts of the "Warrior" section, when it was dismantled, after the experiments upon it.

Another serious objection to wood backing, which I have often referred to, is now proved, by the inexorable logic of facts. It can be set on fire by incendiary shells. I think the advocates of wood-backing will acknowledge themselves in error, and for the sake of your readers, who, perhaps, have had too much of this discussion, as well as for the triumph of truth, I shall be glad if that be the case.

WOODEN SHIPS OF WAR.

Another of your correspondents, of a different order, signing "Observer," makes a personal attack on me, under the pretence of taxing me with being "personally opposed to Mr. Reed." There are some so thin-skinned, and so self-satisfied, that they can suffer no notice in disparagement of their acts, words, or demeanour without ascribing it to personal animus. Some carry this feeling so far, that they exercise it vicariously, on behalf of the objects of their admiration. Like the Moslem, who treats as a dog the infidel disbeliever in Mahomed, "Observer" stigmatizes me because I don't believe in wood. Let him search through my writings, he will find my quarrel is not with Mr. Reed, but with his "wooden bottoms." I have said more than once, and I believe, Mr. Reed is a talented, honourable man, who has made a position for himself by perseverance and industry, for which he deserves great credit. But from what has been publicly stated of his career, and which he has not denied, I conclude he is not a practical shipbuilder.

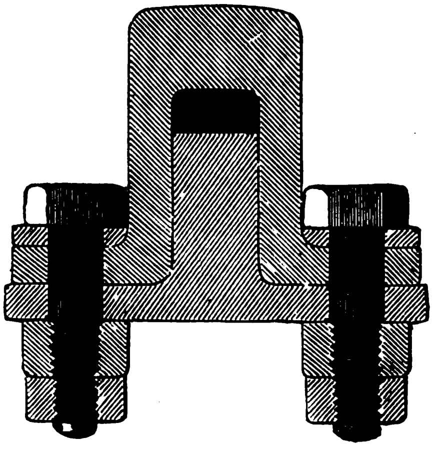
"Observer" is wrong in saying I doubt Mr. Reed's theoretical knowledge of naval architecture. He will not find in anything I have written a word to that effect. On the contrary, I believe I have often stated that his attainments in the theory of that science are considerable; and I think that, if placed in his proper sphere, as a designer, his services will be a great acquisition to the Controller's department. There is a rumour, which I hope may prove true; it is to the effect that Mr. Reed's appointment as Chief Constructor will be revoked, and that of Assistant Controller conferred upon him. Such an office is wanted, and Mr. Reed would fill it worthily. The Controller of the Navy, who, by an odd anomaly, has no knowledge, practical or theoretical, of the art and science of the department over which he presides, must be at a loss to direct the officers whom he controls. He cannot advise; he must be advised by them. He is in the position of a cavalry officer commanding a line-of-battle ship. To have at his side, as the medium of communication with the constructors and master shipwrights, and with the Board of Admiralty, a well-trained and clever assistant, who understands the theory of the profession, must be a great boon to him, and a real benefit to the public service.

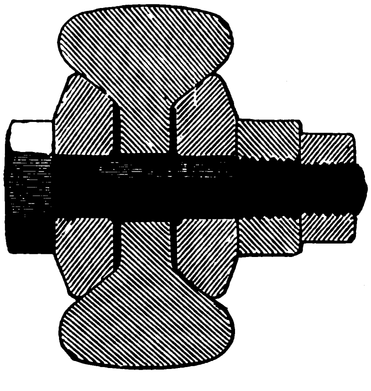
In thus stating in what I think Mr. Reed's real merit consists, I have not a word to retract in respect of his "scheme," or system, if "Observer" likes the latter word better. He inconsiderately exposed himself to attack by stating that his "Enterprise" would be as completely protected as the "Warrior." Knowing that not to be the case, I thought it a duty to disabuse the public by explaining the difference. It is idle to say that an iron-clad is not to be valued by the strength of her armour. If you want cruizers of great speed and with a heavy armament, which can harass the commerce of the enemy, and save themselves by flight from the attack of iron-clads, dispense with armour altogether, and you have an "Alabama" to sweep the seas and carry the "flag of Old England to the Antipodes." If you want light cavalry, don't mount small men on heavy chargers, and overwhelm them with cuirasses. "Observer" must not suppose that Mr. Reed is the only designer of fast ships under 1,000 tons. The sea-going properties of the vessels he has designed have yet to be proved, and sanguine as his friend "Observer" may be, many shipbuilders are doubtful of their success. I am glad to see there is a wholesome dread of an "Enterprise" target trial. At the meeting of naval architects, Mr. Reed deprecated such a trial, because he said it was well known the resisting force of an "Enterprise" broadside was not equal to a "Warrior's." Then why did he ever lead the public to infer that it was? This shows I hit the right nail on the head in mooting the proposition to construct a target. Admiral Halsted I am glad to find endorses my recommendation. I am also in good company in suspecting the Admiralty of proclivities for wood detrimental to the public service. Mr. Cobden, Mr. Laird, and Mr. Lindsay go quite as far as I ever ventured in condemnation and suspicion of their intentions and motives. The debate in Parliament, on the question of the best material for ships of war, will not, I hope, be set down as "fierce partizanship and one-sided reasoning." For my part, I am so satisfied with it as conclusive evidence that I have not misled your readers, and so will the country be, that whoever may be my assailant, I will not encumber your pages with further arguments in support of "wood *versus* iron." The "scientific problem," as "Observer" terms it, is now solved as clearly and unmistakeably as the planetary system.

CIVILIAN.

FALKINER'S METHOD OF FASTENING RAILS AND FISH-PLATES.

The annexed engravings show an improved method of securing the fish-plates of railways, recently patented by Mr. T. H. Falkiner, of Dublin. The improvement, consists in forming upon the ends of the bolts employed two screwed portions or lengths, as clearly indicated, the one being of larger diameter than the other, and the threads on each portion being in reverse directions, the one portion being a right and the other a left hand thread. On each of these portions a nut corresponding to it is screwed, that on the inner screwed portion serving as the ordinary or tightening nut, whilst that on the outer portion (which is of lesser diameter) being screwed in the reverse direction serves the combined purposes of jamming the inner nut and of counteracting the tendency of the bolts to turn loose.





BARRETT'S PATENT FOR CASTING RAILWAY CHAIRS.

When making a mould for the casting of a chair and sleeper known as "Greaves," and which we illustrate in fig. 1 of the annexed engravings, through which the bars are passed, cores are used to produce the requisite holes. The invention which is shown at fig. 2 has been patented by Mr. W. Barrett, of Norton Furnaces, near Stockton-on-Tees. It consists in making the core in two parts, one part of iron and the other of sand, as represented. The portion which is of iron is (when covered with loam) moulded in the upper box on the convex surface, which produces the hollow of the sleeper; the portion which is of sand is produced in the lower box in the same manner as the other parts of the mould. Thus it will be seen that the core is formed complete in the upper and lower boxes, and has not, as heretofore, to be laid in as a separate piece between the two after the pattern has been drawn, and the mould is otherwise complete.

By this method the holes are cast perfectly clean and true, and require no fitting or filling, as the tie-bar will pass through the holes readily,

FIG. I.

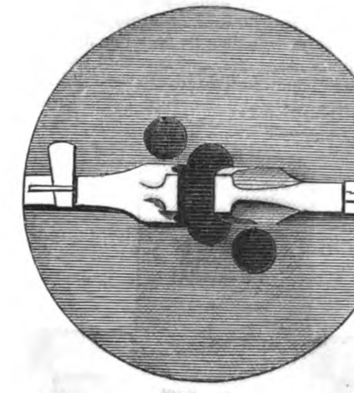


FIG. 2.

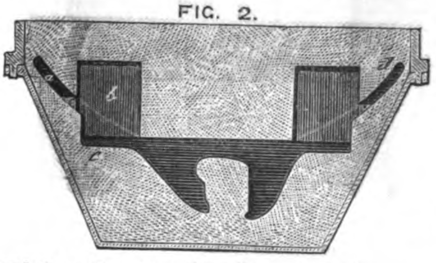

and the ends where the gibs and cotters come are also as true as possible. Time and labour also is saved in the moulding.

Meetings for the Week.

Mon.—*Royal Inst.*—General Monthly Meeting, at 3 p.m.
Soc. of Eng.—Continued Discussion on Mr. Colburn's Paper "On the Relation between the Safe Load and the ultimate Strength of Iron," at 7 p.m.
Medical.—Clinical Discussion, at 8.30 p.m.

Gossip.

The Iron-plate Committee, consisting of Col. Henderson, R.A., Dr. Perry, Mr. Pole, and Capt. Harrison, R.A., assembled on Wednesday, in Woolwich Dockyard, for the purpose of inspecting the process for bending and preparing the coating of the "Caledonia." The committee arrived at half-past one, and having been attended by Mr. Turner and Mr. Thornton, master and asistant-master shipwright, and other officers of the department, they inspected the hydraulic presses and machinery, and examined with careful attention the method by which the heavy slabs of iron are reduced and curved with the most minute accuracy to the form necessary to fit the spot allotted on the ship's sides. The work is progressing speedily and with much success, 120 plates having been affixed to the "Caledonia" without a single mishap occurring, and in a manner which called forth the admiration of the committee. For some weeks past the "Caledonia" has been inspected by many eminent shipbuilders, who have expressed their opinion that the utmost ingenuity and intelligence are observable in the entire construction. Eighty additional hands have been added to the number employed, in order to hasten pletion of the work.

On Monday evening, a meeting of the members of the Inventors' Institute was held at the Polytechnic, Regent-street. Sir John S. Lillie occupied the chair, and the subject for consideration was "Inventions for obtaining aerated fresh water from sea water," which was introduced by Dr. Normandy. The doctor in his prefatory remarks explained the chief objects of the Inventors' Institute. It assisted in bringing before the public inventions worthy of being known. He then explained the old means which had been adopted to obtain fresh water from sea water. The result was, an imperfectly aerated water which was vapid and indigestible. He next went on to show the system he had introduced for the purpose of getting aerated water from sea water. The water so obtained he described as being pure, sweet, wholesome, and immediately fit for drinking. The lecture was illustrated by numerous experiments, and it met with a favourable reception.

A very curious chemical discovery has been made by Dissenbacher, a young German chemist. By the addition of a small quantity of chlorine or iodine, pure sulphur is rendered perfectly soft; and the Paris Academy, to whom the experiment was exhibited by H. Deville, were astonished to see a thin leaf of sulphur treated as flexible as if made of wax.

The costs incurred by the Admiralty in defending the action brought against them by Mr. Clare, for infringement of patent, amounted to £2,143, exclusive of the expense of a dozen witnesses who have not sent in their claims.

Several trials have taken place during the past week at the Royal Clarence Victualling-yard, Gosport, with Mr. Grant's patent oven, ordered by the Lords of the Admiralty to be fitted on board the "Hannibal" screw line-of-battle ship, depôt ship for the Royal Navy, at Portsmouth. The oven, which is made of iron exclusively, is capable of baking at one time about 500 lb. of meat or 300 lb. of soft bread. The trials carried out with both bread and meat have been most satisfactory. All parts of the oven have been found to possess a uniform temperature. When the meat has been served up in dishes from the oven it has been found cooked in a manner superior even to meat roasted carefully in front of a fire, the juices of the meat being more perfectly retained, and the waste in weight being very much less than with meat roasted.

The 5½-inch French armour-plate which was tested at Portsmouth on the 20th of March last, in company with a 4½-inch French plate and some English plates, and which stood the trial in an apparently successful manner, on the 27th and 30th of March, has been unbolted from the side of the "Powerful" target-ship, where it was tested, and removed to the erecting-shop of the steam factory in the dockyard. There a portion of the plate is being cut off by machinery by order of the Admiralty, for the inspection by the members of the Special Committee, now sitting on iron armour. Now that both sides of the plate can be seen, the damage inflicted is found to be much more serious than had been supposed. The peculiarly soft, spreading appearance which the metal of this plate had when struck by the shot on its obverse side, did not raise any apprehensions of serious injury to its reverse, beyond the ordinary and inevitable bulging of the metal. An inspection of the plate now, however, reveals the full extent of the damage the plate has received, and the rupture and separation of the metal is much greater than has been the case with some of the best English plates which have been tested at Portsmouth, the latter being, it is true, selected from some hundreds of trials, but, then, as has been before observed, the history of these French plates is not yet known. The 5½-inch plate had five shots planted in a space of 17 in. by 12. On now examining the reverse, or back of the plate, there is found behind these five shot-marks an irregular oval figure, 18 in. wide and 25 in. in length, where the metal has entirely broken away from the body of the plate to an average depth of 2 in., large cross fissures at the same time extending across the plates, bulging right through to where the shots struck, the apparent damage to the plate being, no doubt, considerably lessened by the spread of the metal before referred to. At the fracture of the metal upon the plate's reverse there is a peculiarly bright, soft, or lead-like appearance; but the layers of metal (the plate is a rolled one) are very much opened. On the upper edge the plate was struck by a single shot, the whole circumference of the blow being on the plate's surface and clear of the edge, but on a bolthole. Here the back of the plate, in the immediate vicinity of the blow, is entirely broken up and rendered useless for all defensive purposes. The body of the plate on the edge has opened up, the welding being, as stated in the report of the trial, very imperfect, and a semi-circular fracture extends from the edge 9½ in. in depth, the chord of the arc being nearly 2 ft. In cutting the piece out of this plate for the Special Committee the iron was found to be unusually hard, taking off the edge of the cutting tool in a manner that surprised the workmen engaged upon the work. It must be borne in mind that this 5½ inch plate was imperfectly welded in its manufacture, and that the 4½ inch apparently stood the best, comparatively, in the trial.

The Patent Ventilating Granary Company (Limited) have obtained their stipulated capital. One of the main objects of the directors is to induce the corn trade to build granaries in the United Kingdom on the new system, either directly, through the intervention of the company, or through licenses to be granted by it. The model granary is now in full work, and contains 1,200 quarters of wheat.

I (says Capt. J. Harvey in a letter), contend, as I have for many years past, that supremacy upon the ocean will mainly depend upon the speed of vessels —not upon their magnitude, structure, or heavy armament of cannon. It would, I believe, be something like certain destruction to any monster war vessel to pursue such a vessel as the Confederate rover if she were armed with submarine explosive shells in addition to her cannon, presuming that such shells are cf some simple form, of easy application, properly charged, and the management of them thoroughly understood. With regard to the speed of vessels adapted to the service of shells, they would, I think, have, in the attainment of that essential, a great advantage over vessels of ordinary form. The upper or weather deck of a shell vessel would be perfectly flush, with no bulwark above it; only stanchions and nettings to prevent those on deck from falling overboard, with weather cloths when needed; there should be nothing to hold wind that might be detrimental to speed. Shell vessels might in addition to their principal arm, have one or two guns to bring-to a merchadise or unarmed vessel. The gun, or guns, when used for such or any other purpose, would be hoisted up from the main deck on to the upper or weather deck, and fired over all. Vessels so completely covered-in would be enabled to encounter, without risk of foundering, any amount of rough weather. Sails, under such conditions need not be used, neither would steam be required, for the vessel's bow may be kept as near to the wind as may be desired by the use of a float anchor, and, so bowing the sea, would avoid the dangers incidental to lying-to under canvas. Shell vessels for home service should, I think, be wholly constructed of iron; while for foreign service I should, in the present difficulty of preventing corrosion and fouling of iron vessels for long periods, very much prefer wood and copper in the construction of shell vessels intended for foreign service or long cruises. Vessels on such service would be accompanied by "a waggon train" of vessels of burden to carry supplies.

A Destructive Shell.—During an engagement between the steamer "Mercedita" and the ram "Palmetto State," off the harbour of Charleston, a shell of 100 lbs. weight passed through the steamer, cutting one man in two, and by going through the steam chimney three men were scalded to death, three others badly scalded, and a number slightly. It passed out the port side, destroying six planks and two timbers, making a clear hole 3 ft. by 2½ft. and shattering the planks 8 or 9 ft. further. The shell exploded as it passed out. It is the opinion of the steamer's officers that, had there been a swell of the sea at the time, she must have gone to the bottom like a stone.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

The Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

Steam Engines, &c., 2428.
Boilers and Furnaces, 2429, 2430, 2468, 2477.

Roads and Vehicles, including railway plant and carriages, saddlery and harness, &c., 2444, 2449, 2475.
Ships and Boats, including their fittings, 2454, 2476.
Cultivation of the Soil, including agricultural implements and machines—*none.*
Food and Beverages, including apparatus for preparing food for men and animals, 2434, 2460.
Fibrous Fabrics, including machinery for treating fibres, pulp, paper, &c., 2433, 2437, 2448, 2451, 2461, 2463, 2471, 2472, 2474.
Buildings and Building Materials, 2447, 2450.
Lighting, Heating, and Ventilating, 2436, 2453, 2457.
Furniture and Apparel, including household utensils, time-keepers, jewellery, musical instruments, &c., 2438, 2439, 2440, 2443, 2455, 2458, 2478.
Metals, including apparatus for their manufacture, 2470.
Chemistry and Photography, 2459, 2462.
Electrical Apparatus, 2431, 2432, 2442.
Warfare, 2435, 2445, 2465, 2466, 2473.
Letter-Press Printing—*none.*
Miscellaneous, 2427, 2441, 2446, 2452, 2456, 2464, 2467, 2469.

2427. H. R. Trigg. *An improved fire escape.* Dated September 2, 1862.

This invention consists principally of a rope, chain, or otherwise-jointed ladder, the round being made of some hard material to keep the sides extended; under this ladder and attached thereto is a prepared canvas trough; they are conjointly made to revolve on an iron axle fixed in a light and ornamental casing, fixed over the window head inside the room; it is so arranged that it will upon turning a button unwind itself; the axle is provided with a break to prevent the ladder descending too quickly. When this ladder is down, a person can ascend at the same time as another party is descending. *Patent abandoned.*

2428. R. Glanville. *Improvements in marine and other engines.* Dated September 2, 1862.

This invention relates to the making use of the heat that radiates through the high pressure steam cylinder as a means of preserving the temperature of the steam in the expansive steam cylinder, and also in economizing space. To accomplish this, the patentee places a series of cylinders within each other, and connects them by their flanches and covers (or cover and bottom, the term being synonymous), and causes the pistons to move simultaneously. He connects the piston rods to a cross head connecting-rod, which operates on one crank. The cylinders are charged with steam by the aid of valves so arranged that each piston shall receive the impulse of the steam alternately. The steam first operates on the piston of the central or high-pressure cylinder, then expands into the large one that surrounds it, and is then condensed upon the principle commonly known as Woolf's. An engine thus arranged he denominates an "annular expansive condensing steam engine." *Patent completed.*

2429. R. Waygood. *Improvements in steam boilers.* Dated September 2, 1862.

This invention consists in constructing boilers in which vertical tubes, by preference tapering towards their upper ends, lead the products of combustion directly upon the bottom of a water space extending nearly across the boiler. The products of combustion are caused to ascend over the upper part of the water space, and in doing so, impinge against tubular water spaces. The products of combustion from each side of the transverse water space meet, and, if required, are made to pass upwards through other vertical tubes, impinge against the bottom of another transverse water space, and so on as before, according the height of the boiler. *Patent abandoned.*

2430. W. Roberts. *Improvements in apparatus for regulating the amount of water discharged by a pump, chiefly applicable for regulating the amount of water thrown by a steam fire-engine, or for regulating the amount of water fed to a steam boiler.* Dated September 2, 1862.

Steam fire-engines as at present constructed are only capable of throwing a jet of considerable diameter, and are unable to throw a jet of small dimensions, as if a small jet be used, the speed of the engine is so much reduced that it cannot work properly, and stops on its centres. Now, according to this invention, the patentee (in the case of double acting pumps) makes a passage between the two extremities of the pump cylinder; in this passage a valve is placed, by which the passage can be entirely closed. When the pump is required to throw as large a jet as possible, the valve is closed, but when a small jet is required, the valve is partly opened; a portion only of the water forced by the piston from one end of the cylinder will then pass away through the jet, the remainder passing through the passage, and entering the cylinder at its opposite end, so that a less quantity of water will be drawn through the suction pipe. *Patent abandoned.*

2431. J. B. Thompson. *Improvements in electro-magnetic machines.* Dated September 2, 1862.

This invention consists in a mode of applying the enormous attractive force of the electro-magnet to the movement of machinery. The electro-magnet may be employed directly to produce a rectilinear oscillating motion; but as the force of the electro-magnet is effective only at a very short distance, the oscillations are too short to apply the great power in any beneficial way for moving machinery, hence almost all attempts hitherto made at applying electro-magnetic force have been in rotary engines, but these machines, even when of the largest size, have produced but small effects. The difficulty to be overcome is to apply the direct pull of the magnet, and at the same time to obtain sufficient length of stroke. This the patentee has done by combining a number of electro-magnets into a series, the electro-magnets being placed one beyond the other, and having their opposite poles at very short distances from each other, so that when the current passes the electro-magnets attract simultaneously. By this means he gets the full force of the electro-magnet, and by adding to the number in the series of magnets, he gets any desired length of stroke. This series of magnets is in imitation of a muscle in the animal body, short magnets representing the striæ of the muscles, and they contract in a similar manner, being really an iron muscle. *Patent completed.*

2432. Sir W. O. S. Brooke. *Improvements in the construction of submarine telegraphic cables.* Dated September 2, 1862.

The object of this invention is so to construct a marine telegraphic cable for deep sea lines that its specific gravity, and, consequently, its rate of sinking as it is laid can be regulated with precision; and a farther object of the means of construction which the inventor adopts is the protection at the same time of the telegraphic core against friction and other ordinary causes of mechanical injury. The objects are attained by the use of wooden tubes, which are threaded on to the telegraphic core. For the construction of the tubes American beech is preferred, impregnated with drying oils or melted paraffine under great pressure. The usual length of the tubes is four inches, and the usual diameter one inch, but these dimensions may vary, and other woods may be used. The core is enclosed in hemp or silk lines rendered waterproof and preserved by any suitable preparations, and coated with tape. Between the ends of the wooden tubes are interposed elastic discs or joints of caoutchouc, flexible or vulcanized canvas prepared with caoutchouc, leather or hemp saturated with paraffine, wax, marine glue, or other oleaginous or resinous substances, or other flexible material may be employed, the object being to give flexibility to the cable with due protection to the core. To regulate the rate of sinking, there may be interposed at certain intervals tubes of iron-wood, lignum vitæ, or other dense woods, or of marble, instead of the ordinary tubes of wood lighter than sea-water. *Patent abandoned.*

2433. A. Johnston. *Improvements in machinery for pressing cotton and other materials, and in bands for retaining the same in bales.* Dated September 2, 1862.

The lever presses heretofore used for pressing cotton have usually been arranged in such manner that the cotton to be pressed is fed into a box into which a plunger can be caused by the lever to descend vertically, and a counterbalance weight is used to counterbalance the weight of the plunger and levers connected to it. According to this invention, the patentee combines together two lever presses in such manner that the plunger of one press shall be ascending whilst the plunger of the other press is descending, the two plungers thus balancing each other. He also prefers to arrange each press in such manner that, after the cotton or other material has been compressed by the descending plunger, the bottom of the case in which the material is contained shall be forced upwards by hydraulic pressure, and in order that the levers of each press may in turn come into a suitable position to withstand the pressure thus put on them, he arranges the two combined presses in a special manner. *Patent completed.*

2434. C. Garion. *An improved method of applying heat in the manufacture and refining of sugar, and in malting, hop drying, brewing, distilling, and vinegar-making.* Dated September 3, 1862.

This invention consists in employing hot water or other fluid as the heating medium, the heat being sustained by self-acting circulation through pipes from a boiler, either contiguous to, or at a distance from, and at a lower level than the subject to be acted on. *Patent abandoned.*

2435. H. Elliott. *A new or improved instrument or apparatus for extracting the cases of pin cartridges from breech-loading firearms, and for recapping, recharging, and closing or turning in the said cartridge cases.* Dated September 3, 1862.

This invention consists of an instrument or apparatus composed of the following parts:—A long hook on the end of a rod is jointed by the said rod to a handle of nearly the same form and construction as that of the ordinary pocket cork-screw. When the instrument is closed, the hook occupies the space between the two sides of the handle, and the hook is held firmly both in its open and closed positions by the spring joint. On that end of the rod which is jointed to the handle, two holes are made at right angles to one another, one of the said holes being in the axis of the rod, and the other being situated across the rod. The former hole is screwed and opens into the latter, which is plain. Into the screwed hole a plug is made to screw, which plug serves to force down the charge in recharging the cartridge case, and also serves to take hold of the pin of the cartridge case in withdrawing the said pin from the said case. The plain hole also serves to draw the cartridge case from the barrel by introducing the pin of the cartridge case into the said hole. In the said screwed hole a cupped closer also screws for closing in the end of the cartridge case after it has been charged. In order to recap the cartridge case, the inventor employs a metal cylinder a little less than the interior of the case. The said cylinder has a hole in its axis, up which the hook can be passed. At the top of the cylinder is a lateral hole, through which the percussion cap is passed, and held between two springs. The cylinder, with the hook and cap in it, is passed up the cartridge case, and the hook being pressed up the cylinder, the percussion cap is forced into the recess in the end of the cartridge case. The pin is now placed in the side of the cartridge, and by turning the handle of the hook upon its joint, the said handle may be pressed against the end of the pin, and made to force the said pin into the percussion cap. When the metallic end of the cartridge case has been separated from the paper tube by the discharge, the said metallic end is drawn out by the pin, and the paper tube or case which is left behind is drawn out by the long hook. By the use of the instrument described, a pin cartridge case can be withdrawn from a breech-loading firearm after discharge, and can be recapped and recharged and closed ready to be used again. *Patent abandoned.*

2436. F. C. Bakewell. *Improvements in fire-places and stoves.* (A communication.) Dated September 3, 1862.

This invention consists of certain improvements in fire-places and stoves, to effect the following objects:—1. To obtain more perfect control over the combustion of the fuel, so that the fire may be made to burn up and give out a great amount of heat, or to burn very slowly, as desired. 2. To effect a saving of fuel. 3. To prevent the soot and fine ashes from passing from the chimney and fire-place into the room. The patentee claims—1, the use of air-passages or recesses in the back wall of the grate extending from below the fire-basket to any desired height above the grating on which the fuel is placed. 2, the use of flaps, or other equivalent device, for closing at pleasure the spaces between the grate bars, on which the fuel rests, for the purpose of preventing the rapid combustion of the fuel. 3, the use of a screw placed over the smoke flue for the purpose of preventing the fall of soot and dirt into the apartment, and for conducting those substances to suitable receptacles from which they may be removed from time to time. 4, the combination of the air flue, dust pipes, and screen described, or any of them, with a fire-place or stove, for the purposes set forth. *Patent completed.*

2437. G. Walton. *Improvements in circular box looms.* Dated September 3, 1862.

This invention has for its object the prevention of the recoil of the shuttle box when moved by the ordinary apparatus, in order to bring the shuttles contained therein successively into their required positions for being driven across the loom, and the consequent increase in the speed at which the loom may be worked. For this purpose, a spring catch is adapted, and applied to the ordinary disc, which spring catch is caused to retain the box in the position into which it is brought by the action of the ordinary apparatus, thereby preventing the recoil from the action of the same. *Patent abandoned.*

2438. W. H. Atkinson. *Improvements in studs or fastenings adapted to holding together parts of shirt fronts, wrist bands, collars, gloves, and other articles of wearing apparel.* Dated September 3, 1862.

By one adaptation of this invention the studs are formed in two parts. To one of these parts is applied the shaft or pillar, which is formed hollow, and with an internal neck or shoulder adapted to receive a stem attached to the other part of the stud, which is held therein by means of a spring, with a notch or notches acting on the neck or shoulder of the hollow stem, and capable of being readily acted upon to release them when necessary. By another arrangement the stems of the respective parts are held one within the other by screwing, aided by spring pressure. By another arrangement, a dovetail-piece is applied to the stem or shaft of one part of the stud adapted to slide into a corresponding recess in the other part, and to be retained there by a spring. By these means a simple round eyelet-hole will alone be necessary, in place of the long button hole now used to receive such studs. *Patent abandoned.*

2439. W. Clark. *Improvements in musical instruments.* (A communication.) Dated September 3, 1862.

This invention consists—1, In the application of an inner tube capable of receiving rotary motion to musical instruments, such as hautboys, flutes, clarionets, and others, and serving to produce the chromatic scale. 2, In the application of an exterior cylindrical tube sliding in either direction, also serving to produce the chromatic scale. By these means the inventor is enabled to produce several tones with the same instrument without change of the fingering. According to the first method each key has two actions or two stops for an instrument with two tones, such as a hautboy, flute, or clarionet, and when one or other tone is played all the holes of the other tone are closed by rotating the interior tube. In the second arrangement, the cylindrical exterior tube which slides up and down the instrument also produces the chromatic scale by the application of a double row of holes in the body of the instrument, in such manner that, by sliding the exterior tube up the instrument, the latter will be raised a half tone higher, and by sliding it in the contrary direction, the first row of holes being closed, those holes which remain uncovered return the instrument to a lower tone. In the latter arrangement, the parts are very simple, and the same as those in ordinary use. *Patent abandoned.*

2440. E. Dyson. *Improvements in throstle spinning and doubling machines.* Dated September 3, 1862.

This invention relates to spinning and doubling machines of the character of the throstle, and to such machines as have a moveable spindle rail which also acts as the copping rail. Hitherto in such throstle spinning and doubling frames the moveable spindle and copping rails have been separate and independent of each other, and by the pull of the bands driving the spindles the moveable copping rails have been forced entirely to one side, causing considerable friction upon the slides, and unsteady and irregular motion. This invention consists in connecting the moveable spindle rails on each side together by a bar or by brackets secured to the rails, by which means the pull of the bands or force acting upon the spindle rails on one side of the frame, will be counterbalanced by that acting upon the spindle rails on the other side of the frame, and thus friction upon the slides is obviated, and the moveable spindle rails are kept true, steady, and free from irregularities in motion. *Patent completed.*

2441. R. A. Brooman. *Improvements in tools for boring, and in apparatus for working the same.* (A communication.) Dated September 3, 1862.

This consists in the construction and use of tubular tools armed with diamond cutters to which rotary and advancing motions are communicated. *Patent completed.*

2442. R. A. Brooman. *Improvements in apparatus for transmitting electric telegraph messages and signals.* (A communication.) Dated September 3, 1862.

This invention is not described apart from the drawings. *Patent abandoned.*

2443. P. J. Bossard. *Improvements in stoppers for bottles, jars, guns, tubes, and other mouthed articles in taps, and in fixing them in casks and other vessels.* (A communication.) Dated September 3, 1862.

This invention is not fully described apart from the drawings. *Patent completed.*

2444. J. Cook. *Improvements in carriages.* ' Dated September 4, 1862.

This invention consists in constructing two-wheeled carriages so as to admit of their being coupled longitudinally, and employed together as four-wheeled carriages, space being left between the couplings of the fore and hind wheels for the object of the lock or turning, whereby wheels of a large and uniform size may be used throughout in connection with cranked or plain axles, and the said carriages coupled either singly or in sets. *Patent abandoned.*

2445. B. F. Cowan. *Improvements in cannon and other firearms.* Dated September 4, 1862.

In carrying out this invention the patentee employs a loading chamber or cartridge case, which he calls a thimble, because it has the general shape of a thimble. This thimble is a hollow metallic or other suitable tube, open at one end, that towards the muzzle of the gun, and closed at the other end, that towards the breech of the gun. The sides of this thimble taper slightly towards the open end. There are two or more slits in the sides of the thimble, running from its open end towards the breech end, but stopping at a suitable distance from the breech end, so as not materially to diminish the strength of the breach end. These slits of course make the sides of the thimble more or less flexible, so that the bore of the thimble towards its open end can be expanded by an internal or contracted by an external force. This thimble contains the whole of the charge of powder or other explosive material, and may contain also, as may be found convenient, the whole or the rear portion of the projectile or shot. When the explosion takes place, the gases thereby generated expand the thimble, and cause a proportionate amount of frictional pressure against the breech chamber, that is, the inner surface of the sides of the gun surrounding the thimble, so that the expansive force of the ignited charge is thus employed to counteract its tendency backwards. He further secures the thimble in its place by some suitable external application. The charge may be exploded in any of the usual ways; but he prefers the central forward ignition, and a thimble so arranged may be applied to any of the existing breech-loading small-arms, which are fitted for central ignition. For the purpose of obtaining such ignition he employs the second part of the invention, which consists in the nipple, or other conductor of the spark to the powder, being so placed, or so arranged that the charge is ignited at the centre of its front portion. When so ignited the expansion of the thimble is obtained most rapidly, and no portion of the charge can be blown out of the gun without being ignited, while the fouling is also left in the thimble and removed with it. The piece is discharged by withdrawing the mandril so far as is requisite, and thus releasing it, on which it is forced forwards by the spiral spring, so as to strike and explode the cap. If it is desired, by adding on to the mandril a stud working into a slot in the handle, the piece can be placed either at half or at full cock. *Patent completed.*

2446. W. Clark. *Improvements in the manufacture of colouring matters.* (A communication.) Dated September 4, 1862.

For the purposes of this invention the inventor takes equal parts of aniline, red and crystallized tolnidine, and heats them for five or six hours at a temperature not exceeding 324 deg. of Fahrenheit, and of not less than 270 deg., after which time a paste of a beautiful blue colour is produced, of a slightly violet hue. This raw paste contains besides the blue colouring matter traces of red which has not become changed, and also an excess of tolnidine. In order to purify it, he boils the paste with dilute sulphuric or muriatic acids, which form salts very soluble in tolindine and red aniline, without injuring the blue. A mixture of one part of common muriatic acid with eight or ten parts of water is preferable for effecting this purification. The matters are boiled in the diluted acid until there is no longer any trace of red colour in the washing waters. The insoluble residue will be pure blue, which may be used for dyeing and printing. *Patent completed.*

2447. J. Platt and W. Richardson. *Improvements applicable to the burning of bricks, tiles, and other articles of earthenware.* Dated September 4, 1862.

This invention consists in a method of heating a filled kiln in a preparatory manner, and this the patentees accomplish by transferring thereto the heat from a separate kiln in which the burning of the bricks or other articles has been effected. For this purpose they employ a blast of air which passes from the top of the heated kiln to the lower part of that in which the articles to be burnt are placed. *Patent completed.*

2448. H. L. Emery. *Improved machinery for ginning cotton.* Dated September 4, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2449. R. P. Coles. *Improvements in the construction of the permanent way of railways.* Dated September 4, 1862.

This invention relates to an improved railway chair, and the mode of securing the same in the permanentyway of railways, whereby greater steadiness and durabilit is obtained, and the cost of maintaining and renewing the permanent way of railways is considerably reduced. This invention proposes the use of an iron chair (cast iron is preferred) made hollow in the upper part, and slightly tapering upwards in the transverse section; into this hollow are fitted two wooden wedges, the upper one entirely fitting into the upper portion of the cavity of the chair, and is forced into its position by the lower wedge (it is preferred that the wedges are kiln dried). The chair with its inclined wedges is then to be placed at intervals, and embedded in concrete of the ordinary composition, and made level with the upper surface of the chair, and forming a continuous bearing surface for the support of any of the well-known flanged rails. Through the flange of the rails screws are passed, securing the rails to the wedges in the upper portion of the chair, and between the flange of the rails and the concrete is interposed a continuous surface of wood or other elastic packing, to relieve the concussive action of the passing load. At intervals, wrought-iron tie-rods are made to pass through holes in the two corresponding chairs, and secured by a nut, to prevent the lateral spread of the gauge. *Patent completed.*

2450. J. Platt and W. Richardson. *Improvements in the preparation of clay for the manufacture of bricks, tiles, and other articles which may be made of such material.* Dated September 4, 1862.

The apparatus for carrying out this invention is not described apart from the drawings. *Patent completed.*

2451. W. Slater and W. R. Harris. *Improvements in self-stripping carding engines for preparing cotton or other fibrous substances or materials.* Dated September 5, 1862.

This invention relates to those machines known as self-stripping carding engines, and consists in the employment of a combination of mechanism for the purpose of raising and lowering the top flats of carding engines at a varying rate or speed, namely, to raise and lower and strip or clean those which are nearest to the "licker-in" or feed rollers at a quicker rate than those which are nearest to the doffer. *Patent abandoned.*

2452. W. E. Bovill. *An improvement in the mode of applying oil and other fluid lubricators to machinery.* (A communication.) Dated September 5, 1862.

The oil cup is, according to this invention, either formed or fixed under or at a lower level than the axle-bearing or machinery to which the oil or other fluid lubricating matter is to be applied. A wick or pad, or several wicks or pads, or a combination of both, possessing the property of capillary attraction, is inserted in the oil cup or reservoir, so that one end of the wick or pad shall touch the axle-bearing or machinery to be lubricated, and the other end shall dip into and absorb the oil or other lubricating matter. The wick or pad is supported by a collar or case of wood, metal, leather, or any rigid substance, and is kept in its place and in constant contact with the axle-bearing or machinery to be lubricated by a spring and guide, or other mechanical contrivance. The wick should, therefore, be made as narrow as possible, and supported and stiffened by the collar or case. And such oil cup or reservoir is to be made with a sloping bottom, and an aperture in the lower part closed by a screw plug, or any suitable mechanical contrivance, so that the detritus, dust, or other impurities may settle in the lowest part, and so as to allow the cup or reservoir to be cleansed when requisite, without dismounting the axle-bearing or machinery or the cup. *Patent completed.*

2453. H. W. Hart. *Improvements in argand and other burners.* Dated September 5, 1862.

An extension of time for filing the final specification of this patent having been petitioned for, the documents relating to the invention cannot at present be seen. *Patent completed.*

2454. D. R. Samuel. *Improvements in apparatus for steering vessels.* Dated September 5, 1862.

In carrying out this invention, the inventor proposes to reverse the tiller of the rudder by making it point "aft" instead of "fore," as is usual, the end of the tiller being provided with a vertical pin and roller which acts in a groove cut in a double-action lever; this lever works on a centre pivot, and is forked at its fore-end so as to receive a block of metal to slide in slots, through which block a screw works, being set in bearings on each side of the deck; thus, when motion is imparted to the screw by means of a steering wheel, the block and lever are brought from the centre of the ship to the side required, and, consequently, the rudder is turned accordingly by the other extremity of the lever, the greater power being gained where most required, the difference in the lever being greater as the rudder is moved towards either side. The steering wheel may either be attached to the end of the screw at the side of the ship, or may be placed in the centre of the deck, bevelled wheels being employed to actuate the screw. *Patent abandoned.*

2455. J. S. Margetson. *Improvements in the manufacture of the material intended for scarfs or cravats, and the machinery employed therein.* Dated September 5, 1862.

In carrying out this invention, the patentee arranges in the loom a single warp of fine silk or other material, and he forms a double series of wefts of silk or other material of the various desired colours, wound on bobbins in shuttles, one series of such shuttles being worked on a higher lever than the others, and which are thrown across the warp by hand or steam power, whereby the warp is buried between the wefts, and a different series of stripes and colours is produced on each side of the fabric, according to the colours of silk or other materials in the shuttles; and in some cases he employs gold or silver thread to form some of the stripes. The result of this arrangement is that he produces a twilled fabric twilled on both sides, having a striped pattern of any number of colours, and of various widths on both sides of the cloth, the patterns being totally different from each other. *Patent completed.*

2456. W. Wells. *Improvements in horse shoes and in the method of fastening the same.* Dated September 5, 1862.

In carrying out this invention the inventor proposes to form a plate or false shoe of malleable iron, of the size and form of the hoof, the same having holes pierced therein corresponding with those in the shoe itself; the shoe is to be nailed to this plate, and the ends of the nails turned over and broken off, thus securing the shoe to the plate. This plate has side clips and a toe clip, the toe clip being pierced with a hole for the purpose hereafter described; the back of the plate or false shoe is provided with a metallic strap, on one side of which is a stud, and on the other a boss through which a screw passes; this screw works into a nut on a band passing from the lower part of the heel round the upper and front part of the hoof, the other end of the said band passing over the stud before-mentioned; the band is also pierced in front to allow of a hook to pass from it down to the front of the plate or false shoe, so that when the screw is actuated the plate band and hoof become simultaneously tightened. *Patent abandoned.*

2457. W. E. Newton. *Improvements in lamps.* (A communication.) Dated September 5, 1862.

The object of this invention is to construct a lamp adapted to convert hydro-carbon oil, camphine, or other liquid lighting material into gas, and to burn the gaseous product in a separate illuminating frame apart from the wick without the use of a chimney. The invention particularly consists—1, in an improved manner of forming and applying the deflector by which air is furnished to the flame in the most advantageous direction and condition. The invention consists, 2, in an improved device for supporting the deflector adjustably upon the wick tube; 3, in a device for supporting a reflector or other article to be used in connection with the lamp or a nursery cup or vessel to contain water or liquid that may be heated by the flame of the lamp. *Patent completed.*

2458. S. H. Hadley. *An improved process for manufacturing gas for illumination.* Dated September 5, 1862.

The patentee claims the production of permanent illuminating gas by the decomposition of steam and volatile hydro-carbon in the state of vapour, the steam and hydro-carbon vapour being mixed while the hydro-carbon is in the nascent state by subjecting such mixture to the action of red hot carbon as described. *Patent completed.*

2459. J. R. Johnson and J. A. Harrison. *Improvements in apparatus for taking photographic panoramic pictures.* Dated September 5, 1862.

This invention consists, 1, in an improved construction and arrangement of the parts of the flat plate camera, so that their motions are smooth and free from vibration, and so that the whole apparatus is rendered more compact and portable than those previously suggested. 2, in a new mode or modes of obtaining the relative motions of the lens and sensitive plate, such motion being obtained directly by mechanical means, or by appliances constructed mechanically instead of by guide curves or grooves formed by trial, as has heretofore been proposed to be done. 3, in an improvement in the gearing when working both forms of camera. 4, in the application of a spring or weight to give motion to such cameras, and in means for regulating such motion both at variable and invariable rates. 5, in the application of an expanding diaphragm to regulate the exposure in cameras moving at an invariable rate. 6, in an expanding diaphragm to be placed between the lens and the sensitive plate, by means of which sky and cloud effects may be obtained, and by which the amount of exposure may also be regulated. *Patent completed.*

2460. S. H. Huntley. *Improvements in cooking apparatus, more particularly applicable to the requirements of the army and navy.* Dated September 6, 1862.

The patentee claims—1, the construction of cooking apparatus having two or more boilers, and one or more ovens placed between the boilers, and in which both the boilers and the oven or ovens are heated by the same fire or fires, substantially as described with reference to the drawings. Also the combination of such apparatus with a hot plate or open fire for roasting and boiling. 2, the construction of cooking apparatus in which two or more boilers are fixed inside a casing, and an oven or ovens above and between the boilers, access being gained to the boilers on either side of the oven or ovens, and in which the draught from the fire or fires is caused first to pass along the bottom surface of the boilers, and then to cirtulate over the greater part of the surfaces of the oven or ovens on its way to the chimney. Also, the adaptation of such apparatus to field purposes by affixing a store box, wheels, and shafts to the same. *Patent completed.*

2461. J. Schnider. *A new and useful method of increasing the durability of, and for preserving, cloths and other like fabrics used for sails, tarpaulings, tents, and other coverings, &c.* Dated September 6, 1862.

This invention consists in applying to the above, and various other fabrics, a composition, or paint, of which graphite is the chief base. *Patent completed.*

2462. S. Pudney. *Improvements in apparatus to be used in the manufacture of sulphuric acid.* Dated September 6, 1862.

This invention consists in improvements in the construction of sulphuric acid chambers. These chambers are commonly constructed of sheet lead, the floor, walls, and roof of the chamber being of this material. Now, according to this invention, the patentee employs sheets of glass in the construction of the parts of the chamber. We cannot quote the details. *Patent completed.*

2463. H. Hughes. *An improved frilled and fluted fabric or material, and improvements in fluting or goffering machines.* Dated September 6, 1863.

The improved frilled and goffered fabric is composed of a material, say ribbon; it may be all of one colour, or of different colours, and may be made of similar or dissimilar materials, that is to say, for example, the body may be made of velvet and the edge or edges of silk, or the body of linen and the edge or edges of cambric, or the whole may be made of paper. The patentee forms the improved fabric by goffering the material which is to constitute the the edge or edges of the material in a goffering machine with plaits or goffers; and next sews, by preference, in a sewing machine, the bottom edge of this goffered edging on to one edge of the material which is to form the body, taking care that all the plaits are secured thereto. Both edges of the body may have similar goffered material sewn to them, or one edge only may have the goffered material sewn to it, while the other edge has a piece of plain material sewn to it, or not, as desired. The patentee then takes the body and the goffered edge, and passes the whole through a fluting or goffering machine similar to that for which letters patent were granted to the inventor, May 29 (No. 1327), but with the leaves, or pattern formers, so made as not to injuriously affect the already-goffered edging. The effect is to produce a fluting or goffer across the whole fabric, including the goffered edging. Lastly, the inventor runs one or more rows of stitching through and along the fabric, in order to preserve the fluting. *Patent completed.*

2464. E. L. Duncan. *Improvements in the manufacture of splints.* Dated September 6, 1862.

In carrying out this invention, the patentee proposes to form splints of a strong fabric padded with wool or cotton wadding, or with layers of any soft fabric; or the padding may in some instances be dispensed with. He also applies and fastens to the back of these splints (in order to maintain their position and strength) any kind of cane, such as ratan, bamboo, or jungle cane, either split or entire, and in longitudinal rows or layers, the cane being sewn in under the material forming the back of the pad, which then presents a fluted or grooved surface; or the cane may be wound or interlaced so as to unite their series in a parallel position, and thus obviate the necessity of padding. *Patent completed.*

2465. J. H. Johnson. *Improvements in firearms and projectiles.* (A communication.) Dated September 6, 1862.

This invention relates to certain improvements in firearms, which improvements are partly applicable to breech-loaders and partly to muzzle-loaders, whether rifled or smooth-bored, and also to a peculiar form of bullet suitable for rifled firearms of all kinds. We cannot quote the details. *Patent completed.*

2466. W. J. Curtis. *An improved construction of breech-loading cannon.* Dated September 6, 1862.

In carrying out this invention, the inventor mounts the breech of the gun within a curved frame, through the forward ends of which pass the trunnions of the barrel or main portion of the gun. This curved frame is further secured to the barrel by a strap piece, whereby, when it is required to elevate or depress the gun, the barrel and frame will rock together on the axis of the trunnions. A vertical adjusting screw from the gun carriage, bearing upon the under side of the curved frame, is provided to effect the vertical adjustment. The sides of the curved frame are pierced with elongated inclined holes, which are intended to receive the trunnions of the moveable breech piece. This breech piece is so hung as to balance itself, or nearly so. This arrangement necessitates but little exertion from the gunner to move it into or out of line with the barrel. On one of the trunnions of the breech piece is a lever, or it may be a spanner, for operating the breech piece, and turning it into a vertical position ready to receive the charge. When charged, the breech piece is again rocked on its trunnions, and having been brought into a line with the barrel, it is forced home by a binding screw that lies in a line with the axis of the gun, and is worked by a hand lever. This screw is tapped into the rear of the curved frame before mentioned, and is operated by a hand lever. It bears in the rear of the breech piece, and its action is to force the breech piece into close contact with the barrel, and thereby close the joint between them. The better to ensure a close joint, a portion of the contact surface may be coned, and thus an interlocking of the parts will be effected. If thought desirable, soft metal packing may be introduced between the contact surfaces. *Patent abandoned.*

2467. W. A. Richards. *An improved fastening.* Dated September 6, 1862.

One portion or member of this fastening consists of three plates, two of which are fixed, but the outermost or uppermost is capable of sliding to and fro on or over the next, and carries on its under or inner side a slotted piece which projects through an aperture in the second or middle plate, and works on or over the third plate, the plates being disposed accordingly. This slotted piece is so constructed that there is a recess or space between its slotted part or surface and the sliding plate that carries it. The slot in the projection is of a shape resembling a keyhole, having a narrow portion leading into a broader portion. The third plate which is the undermost or innermost has also an opening or orifice in it. The other portion or member of the fastening is a catch, pin, stud, hook, or piece hereinafter called "catch" or "pin," which the patentee prefers to form as a pin or stud with lateral recesses or niches in the body. The aperture in the third or undermost or innermost plate is of sufficient size to admit the head top or free end of the catch. To close the fastening, this head top or end is first admitted through the third plate, and through the broad portion of the slot in the slotted piece, and the sliding piece is then moved so as to bring the narrow portion of the slot over this aperture. While in this position the plates cannot be released from the catch. To open the fastening, the sliding piece is moved to bring the broader portion of its slot over the opening in the undermost or innermost plate, whereupon the plates will be disengaged from the catch. *Patent completed.*

2468. C. W. Williams. *Improvements in steam boilers.* Dated September 8, 1862.

This invention is designed to increase the evaporative or vapourizing effect of steam boilers, and consists in substituting for the ordinary long tubes or flues employed in locomotive marine and other steam boilers, sets or series of short tubes or flues of a circular, rectangular, or other form at short distances apart, the ends of each set or series being fitted into tube plates or face plates, like those into which the long tubes aforesaid are united. The object of this arrangement is to increase the number of tube plates or face plates against which the flame of hot gases generated in the furnace strike, as the patentee has found by experiment that tube plate or face plated surface exposed to the direct action of the flame and hot gases is much more efficient than the interior surface of the tubes themselves in transmitting heat to the water within the boiler. *Patent completed.*

2469. F. D. Artingstall. *Improvements in balances.* Dated September 8, 1862.

This invention relates to weighing machines and other balances, and consists in employing thin plates of steel or other suitable metal instead of the knife-edged centres now generally used. The said plates bear the weight above them by thrusting, and as the plates are flexible they allow motion to the levers or arms of the balance or steelyard, but as that motion is only delicate through a small space or angle which it is difficult to perceive, the patentee makes it the more clearly perceptible by fixing to the arm of the steelyard or balance a spirit level, which indicates a very small disturbance of the level or equilibrium. Or he employs a multiplying lever to multiply the motion of the balance by making the head of the balance high and heavy. *Patent completed.*

2470. J. S. Crosland. *Improvements in the manufacture of tubes made of copper, and of copper combined with other metals.* Dated September 8, 1862.

This invention consists in casting the said tubes in hot dry sand, or hot metal moulds, with hot dry sand or loam cores in a vertical or inclined position, pouring the metal into the mould from the top; chaplets or thickness stops or wedges of copper or other metal are placed between the core and the mould. *Patent abandoned.*

2471. J. Whitehead. *Certain improvements in looms for weaving.* Dated September 8, 1862.

This invention consists—1, in certain improvements on a former patent granted to the present patentee on the 10th day of June, 1861 (No. 1470), whereby the chain drums referred to in the specification of the said patent may be moved in either direction, backwards or forwards, as may be required. 2, in an arrangement of mechanism for varying the quantity of fabric taken up, such invention being governed by the shuttle-box then in working condition. 3, in an arrangement of mechanism for preventing the stopping of the loom by the weft fork when the weft is withheld for the purpose of making a fringe, or for other purposes. *Patent completed.*

2472. J. Hartshorn and W. Redgate. *Improvements in means or apparatus for the manufacture of lace fabrics.* Dated September 8, 1862.

This invention relates to means for the production of what are called scolloped edges, and also extensions or contractions to holes and other parts of lace fabrics. For this purpose, in addition to the ordinary points, the patentees employ another or other bars of points below the ordinary points, and such extra point bars, in addition to their backward and forward motion are capable of endway motion; regulated by jacquard or other pattern surface, so that these points may operate upon threads to draw them sideways to the extent desired, and they are placed in position to enter between the threads just above the carriages, when the desired endway motion may be given to such extra points to draw the threads sideways till taken and held by the ordinary points, and so on until the desired deviation from the otherwise regular course of threads has been attained. *Patent completed.*

2473. C. Fink. *An improved turbine.* Dated September 8, 1862.

This improved turbine is constructed with a fixed outer ring of adjustable direction vanes, contained between two parallel horizontal annular surfaces, between which adjustable vanes the actuating water passes, and is directed by them into and through a series of buckets or openings formed with or attached to a ring or wheel attached to a shaft or spindle, and free to revolve within the ring first-mentioned. The actuating water, after passing through the buckets of the inner ring or wheel (and twereby giving a rotary motion to the same and to the shaft or spindle upon which it is fixed), passes downward through a suitably-formed pipe or tube, from which it is ultimately led away in any convenient manner. *Patent abandoned.*

2474. G. W. Belding. *Improvements in machines for forcing fluids and dirt from cloth and other fabrics.* (A communication.) Dated September 8, 1862.

This invention relates chiefly to novel means for rendering the machines self-adjusting; to the method of attaching the machines to the washing tub or vessel; and to the arrangement and combination of the parts, whereby the machines are rendered less expensive, and more durable and efficient than those heretofore invented. We cannot here quote the details. *Patent completed.*

2475. G. Davies. *Improvements in railway signals.* (A communication). Dated September 8, 1862.

This invention has for its object the placing beside the rails (at a suitable distance from the stations) of a detonating signal requiring no change of the customary usages, capable of being put in action from the station, and infallible in effect. *Patent abandoned.*

2476. A. J. Alderman. *Improvements in ships' windlasses, capstans, and cable stoppers, applicable generally to hauling and working with chains.* Dated September 8, 1862.

This invention consists, 1, in an improved cable stopper, by which the cable can be held firmly, its paying out checked and controlled, and the ship gradually brought up without any sudden pull or jerk upon the cable. The invention consists, 2, of a whelp of improved construction, by which the overlapping or riding of one link of the chain upon another, and the jamming of the cable against the bits are prevented, and a greater hold of the cable upon the barrel of the windlass is obtained. *Patent completed.*

2477. J. Webster. *Improvements in preventing the incrustation of steam boilers.* Dated September 9, 1862.

This invention consists in placing in steam boilers a surface of tow, hemp, jute, cotton waste, or other fibrous and absorbent substances, wherein the earthy matter caused by evaporation is deposited. *Patent abandoned.*

2478. P. Rainer. *Improvements in watches, chronometers, and other timekeepers.* Dated September 9, 1862.

The object of these improvements is, that whilst the watch, chronometer, or other timekeeper by the hands or pointers is set to indicate Greenwich or other particular time, it may also by the same hands or pointers indicate other local time or times. For this purpose, in addition to a fixed dial for moveable hands or pointers, as heretofore, and which may indicate Greenwich or other particular time, the inventor applies another series of figures upon a separate rim or surface, which may be shifted round the centre of motion of the hands or pointers, and yet be held in grooved or other guides, and retained as set by spring or other stop, so that the respective figures of such extra series may, in their relation to the other set of figures, indicate the difference of time between any two distant places. *Patent abandoned.*

PROVISIONAL PROTECTIONS.

Dated Nov. 15, 1862.

3072. C. Binks, Parliament-street, Westminster. Improved methods of, and apparatus for, treating linseed and other oils and fats.

Dated Feb. 17, 1863.

431. E. Deville, 95, Rue Blanche. Improvements in floating or life-preserving coats or garments. (A communication.)

Dated Feb. 24, 1863.

499. J. Clay, Sparkhill, near Birmingham, saddler. Improvements in the manufacture of saddles.

503. J. W. Burton, Leeds, gentleman. Improvements in the bearings and leashes of axles and shafts.

Dated Feb. 26, 1863.

535. H. Edmonds, M.D., surgeon, Royal Navy, Peel Lodge, Stoke-road, Gosport. Improvements in the ventilation of ships and vessels, and apparatus connected therewith.

Dated Feb. 27, 1863.

550. W. Stauffen, George-street, Portman-square. A new or improved fibrous substitute for human and other hair, to be used for all the purposes for which human and other hair is now used, and also for the manufacture of textile fabrics.

556. R. A. Brooman, 166, Fleet-street, patent agent. A new method of, and apparatus for, boring into water and gas supply pipes, and fixing branch pipes therein. (A communication.)

560. V. D. Delahaye, civil engineer, 7, Cauchoise-street, Rouen. Improvements in apparatus for cleaving and excavating pit coal and rock or earth.

Dated March 2, 1863.

586. W. Clark, 53, Chancery-lane, engineer. Improvements in preparing and obtaining photographic impressions, and in the application of such improvements. (A communication.)

Dated March 3, 1863.

594. G. Price, Cleveland Safe and Lock Works, Wolverhampton, iron safe and lock manufacturer, and W. Dawes, Bolton, engineer. Improvements in burglar-proof safes and strong-room doors and frames.

Dated March 4, 1863.

605. J. De Keyser, Molenbeck St. Jean, Belgium. Improvements in treating petroleum oil, and in the combination thereof with other oils for lubricating and other like purposes.

Dated March 6, 1863.

620. E. P. Plenty and W. Pain, Newbury, Berkshire, agricultural engineers. An improved method of supporting screens and straw shakers, specially applicable to thrashing machines.

636. A. Wilson, 50, Lower Woodbridge-street, Clerkenwell, chair and cabinet maker. The better and more commodious manufacture of all kinds of easy, lounging, and invalid chairs, seats, or settees.

Dated March 9, 1863.

654. Sir A. Keller, Zurich. An improved apparatus for reeling silk direct from cocoons on bobbins.

Dated March 11, 1863.

660. R. T. Monteith, St. Malo, France, British Vice-Consul, R. Monteith, 64, Crystal-terrace, Cecil-street, Greenheys, Manchester, gentleman. Improvements in making dyes from aniline and its analogues. (A communication.)

Dated March 13, 1862.

680. H. B. Barlow, Manchester. Certain improvements in looms for weaving. (A communication.)

682. C. T. and A. Lutwyche, Birmingham, manufacturers. An improvement or improvements in metallic pens.

684. J. B. M. A. Bourreiff, 12, Rue des Petites Ecuries, Paris, manufacturer. Improvements in transferring by means of typography colours and metals on surfaces in general.

686. A. Wydler, Belfield Print Works, near Rochdale, calico printer, and C. Thornton, manager. Improvements in printing and dyeing woollen fabrics.

688. W. Smith, Little Woolstone, farmer. Improvements in machinery for cultivating land and sowing seed.

Dated March 14, 1863.

692. J. Page, Liverpool, civil engineer. Improvements in taps or valves.

694. J. Tangye, Birmingham, manufacturer. Improvements in portable hydraulic punching machines.

696. T. C. Richardson, Swansea, merchant. Improvements in the construction of ships.

698. R. Moreland, jun., Old-street, St. Luke's. Improvements in apparatus for making extracts of hops, and for selecting or separating the seeds and pollen from hops.

700. W. Boaler, Manchester, merchant. Improvements in the preparation of colouring matters for dyeing and printing. (A communication.)

Dated March 16, 1863.

704. W. Vernon, Nottingham, lace manufacturer. A new or improved means or apparatus for communicating signals or intelligence to or from railway trains or other similar conveyances, whether they be stationary or in motion.

706. T. Powell, 30, Prince's-terrace, Regent's-park. An improved chopping block for butchers.

Dated March 17, 1863.

712. W. H. Atkinson, Cavendish Club, Regent-street, gentleman. Improvements in studs or fastenings adapted to holding together parts of shirt fronts, wristbands, collars, gloves, and other articles of wearing apparel.

718. T. N. Miller, Bishop Stortford. Improvements in heating horticultural buildings.

Dated March 18, 1863.

724. F. Richmond, H. Chandler, and J. G. Richmond, Salford, agricultural implement makers. Improvements in machinery for washing potatoes and other vegetables.

726. H. Kilshaw, Haslingden, cotton spinner. Certain improvements in looms for weaving.

730. F. Norrington, Tavistock, Devon. Improvements in girths or bands and knee-caps for horses.

Dated March 19, 1863.

736. H. Wilde, Manchester, engineer. Improvements in the construction of steam boilers.

738. J. Saunders and J. Piper, Cookley Iron Works, Kidderminster. Improvements in apparatus employed in the manufacture of tin and terne plates.

740. C. Webster, New Radford, locksmith, and W. Forgie, Nottingham, lace cap manufacturer. Improvements in apparatus for the purpose of clearing out the interior of foul chimneys when on fire or otherwise.

PATENTS APPLIED FOR WITH COMPLETE SPECIFICATIONS.

Dated March 19, 1862.

734. G. Haseltine, 12, Southampton-buildings, Chancery-lane. Improvements in the manufacture of boots and shoes. (A communication.)

739. S. L. Croker, Taunton, Bristol. A new and useful or approved yellow-metal sheathing nail or spike, which, by means of a nail cutting engine, is cut from yellow sheathing metal.

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

From the *London Gazette*, March 31, 1863.

3085. C. Binks. Obtaining oxygen and chlorine gases.

3159. A. L. Woolf. Metallic alloy.

3168. T. Fletcher. Construction of rollers, cans, spools, and bobbins.

3179. T. Keyworth. Motive-power machinery.

3180. W. T. Rawlett. Machinery used in producing knit or looped fabrics.

3184. W. Clark. Preservation of animal and vegetable substances. (A communication.)

3191. J. Cresswell and E. T. Greves. Construction of hearses and funeral carriages.

3197. A. Dudgeon. Packing for various parts of steam and other engines and machinery.

3223. B. Oldfield. Looms.

3224. A. V. Newton. Construction of steam and other vessels. (A communication.)

3285. P. Todd. Pickers.

3290. J. Hilliar. Hinges, joints, or connections.

3291. J. Hilliar. Ventilating.

3408. A. V. Newton. Automatic toy figures. (A communication.)

18. W. H. Muntz. Iron or other vessels.

154. G. Haycraft. Powder flasks.

391. J. Grantham. Hydraulic presses.

446. G. T. Bousfield. Breech-loading fire arms. (A communication.)

471. C. Malpas. Ovens or kilns.

479. W. Wood. Manufacture of confectionery.

521. W. Readman. Manufacture of carbonate of magnesia.

582. E. Habel. Preparing, spinning, and doubling fibrous substances.

636. A. Wilson. Chairs, seats, or settles.

688. W. Smith. Cultivating land and sowing seed.

731. G. Haseltine. Manufacture of boots and shoes. (A communication.)

739. S. L. Crocker. Yellow metal sheathing nail or spike.

The full titles of the patents in the above list can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners' office particulars in writing of the objection to the application.

LIST OF SEALED PATENTS.

Sealed March 27, 1863.

2647. J. Addison.
2654. A. Prince.
2659. B. Donkin.
2671. R. Broadbent.
2673. W. Clark.
2678. J. and W. Lee.
2680. A. Barclay.
2681. W. E. Gedge.
2686. F. Watkins.
2687. F. E. Blatspiel.
2690. F. Johnson.
2692. R. Page.
2696. S. Holland.
2700. S. F. Cox.
2764. H. Bridson and J. Alcock.
2776. E. Molyneux.
2778. J. H. Jenkinson.
2713. P. Potenza.
2785. F. F. Prud'homme.
2822. N. R. Hall and M. L. Parnell.
3024. W. Clark.

PATENTS ON WHICH THE STAMP DUTY OF £50 HAS BEEN PAID.

778. J. A. Maxwell.
783. J. H. Johnson.
784. J. Church.
798. J. L. Hancock.
805. S. R. Smith.
810. I. Holden.
820. J. Reidy.
826. W. M. Chambers.

PATENTS ON WHICH THE STAMP DUTY OF £100 HAS BEEN PAID.

680. H. Brierley.
692. J. Robertson.
788. W. Roberts.
790. F. Grice.
814. R. Halliwell.

The *Morning Post*, Sept. 29, speaking of Benson's Watches in the Exhibition, says:—"The collection of watches shown by Mr. Benson is a large, and at the same time an interesting one, and considerable attention has been paid by the exhibitor to the decoration of the cases. Many of them are extremely elegant in the design, and were the results of prizes offered by Mr. Benson to the pupils of the South Kensington School of Design." Chronometers, duplex, lever, horizontal, repeaters, centre seconds, keyless, split seconds, and every description of watch, from the plainest to the highest quality of which the art is at present capable, adapted to all climates. Benson's Illustrated Pamphlet on Watches (free by post for two stamps), contains a short history of Watchmaking, with descriptions and prices. It acts as a guide in the purchase of a watch, and enables those who live in Scotland, Ireland, Wales, the Colonies, India, or any part of the world, to select a watch, and have it sent free and safe by post.—J. W. Benson, Prize Medallist, 33 and 34, Ludgate-hill, London. Established 1749.—[Advt.]

LONDON, FRIDAY, APRIL 10, 1863.

UNDERGROUND RAILWAYS.

New inventions seldom spring, Minerva-like, fully armed, prepared to battle their way through the world from the parent brain. More usually they follow the ordinary course of nature, and walk before they can run. Novel schemes, exceptional projects, afford few examples of precocity and, in common with most other matters in this sublunary world of ours, require the finishing touches which old father Time alone can give, ere they can be said to have attained that perfection, necessary to please and ingratiate a public often captious, always critical.

The Metropolitan Railway, unexampled as its success has been, still shows evident traces of that juvenescence common to all new designs; perfect as it is in other respects, it leaves much to be desired in the mode of propulsion; commodious stations, luxurious carriages, civil attendants, an almost perfect immunity from even the chance of accident, locomotion at a fair speed and at a moderate price, are not all the public reqnire. Directors may consider the many-headed monster fastidious, but still he must be satisfied; and there is nothing more sweet to the London public than air, if not fresh, at least wholesome; and the Metropolitan has hitherto proved sadly deficient in supplying the necessary.

The most moderate amount of reflection on the reader's part will convince him of the utter impracticability of getting rid of the products of combustion unavoidably evolved from an ordinary locomotive, in such an effectual way as to permit the atmosphere of this railway to remain pure enough for human use. In consequence engines of very peculiar design, and embracing many novel features of construction, have been hitherto employed to work the traffic. Nearly all the resources of science and talent have been expended on these engines with, we regret to say, very moderate success; and the conviction gradually forces itself on us that, without a further improvement which neither science nor talent at present seem likely to effect, the present mode of propulsion must be abandoned in favour of some other which, perhaps, not so theoretically perfect, will, in practical use, permit the existence of an atmosphere within the tunnel which we can breath freely, unassailed by noxious odours, or tormented by mental associations with the *grotto del cane*, brought on by bodily sensations.

Were the matter to rest where it is, we should not regard it with the same attention as we do when we see that the mighty hand of progress has already laid its iron grasp on the whole subject; already half a dozen Metropolitan—that is, underground—railways are proposed, and join in the favour which the first has received. There appears every likelihood that underground London will be tunnelled and bored by these arteries of communication in every direction; the probability being that few of them will be built with the same attention to ventilation as that now open, or an equal amount of room. The subject of propulsion in such cases becomes of importance to the public at large, and a serious problem for the reflective engineer. When the Liverpool and Manchester Railway was first proposed, this subject met with the greatest attention from the directors, and steam was only adopted after much prudent consideration and careful experiment. With this railway commenced, it is true, a new era of intercommunication on the surface of the earth: with the Metropolitan begins a new era of intercommunication below that surface—an era which certainly presents nearly as many novel points in construction and working detail, for the wise consideration of the engineers of the present day, as ever did the Liverpool and Manchester to their fathers, five-and-thirty years ago.

No mode of propulsion seems to us so likely to suit all the exigencies of such cases as the atmospheric system—a system which we think has been too much "pooh-poohed," and passed over with too much contempt. That it is quite unsuitable for the requirements of an ordinary railway, with the stations at great distances apart and a heavy mixed traffic, every engineer will unhesitatingly admit; but the case is far different with the Metropolitan—a railway of the most moderate length, with the stations close together, and almost exclusively devoted as it is to passenger traffic. For such a line the atmospheric system appears admirably adapted; perfectly safe, providing an admirable means of ventilation, capable of giving the highest speeds ever attained in the annals of locomotion, moderate in cost, and promoting the duration of the permanent way to a degree that those who have not watched its practical operation over a long series of years can scarcely realize. We believe that it only requires a little thoughtful attention to lead to its ultimate adoption.

Many objections can be urged against its use for ordinary railways, objections which we admit to be insurmountable; but only two of these objections will apply to its adoption for such as the Metropolitan—the one, excessive leakage; the other, the difficulty of arresting the train at any particular station. Before referring further to them, we think that a short retrospect of what has been done may not prove uninteresting. In the year 1810, a Mr. Medhurst, a clever London engineer, proposed that mails and passengers should be conveyed in precisely the same way as that now adopted by the Pneumatic Dispatch Company at Battersea; it need hardly be said that at that day his proposal met with total neglect and contempt. We had not yet reached the degree of civilization necessary to satisfy us of the expediency of suffering ourselves to be shot, as it were, through a close-mouthed iron tube! besides which, the cost of the system would be enormous for a long over-ground line. The matter dropped; was revived again by Mr. Pinkus, an American, and finally taken up by Mr. Clegg, who, in conjunction with the late Mr. Samuda, brought the system to a certain amount of practical perfection. They reduced the size of pipe in the manner proposed by Pinkus, and placing it between the rails, placed a piston connected with the train within it, instead of the train itself. The scheme met with such partial favour, that two short lines were laid down on the system—one from London to Croydon, the other from Kingstown to Dalkey, in Ireland; both have been removed, not so much from the failure of the system itself, as many believe, as from the presence of overruling circumstances which compelled the substitution of locomotives. Quite unsuitable as we have already said the atmospheric system is for long railways, each of these short ones found itself swallowed up, as it were, in a few years, by a long one, with hosts of branches and a heavy mixed traffic, so that the original line now forms but a minute fraction where it once formed the whole. It is said that the constant "break downs" of the Croydon stationary engines early brought the system into disfavour then; but that, of course, bore no connection with the merits or demerits of Clegg's design *per se*. The line from Kingstown to Dalkey was worked for many years with perfect success, and a very moderate expense: it was finally absorbed by the Irish South Eastern, which is, of course, worked by locomotives.

As we believe that the principle is pretty well understood, we will not enter deeply into any descriptive details: it is sufficient that we consider the means of overcoming the two objections which we have already alluded to, the first and most important of which is the leakage at the longitudinal valve, and consequent waste of power in pumping; now it must be remembered that, twenty years ago, it was found almost impossible to overcome many difficulties in which the modern engineer sees no difficulties at all; it is only necessary to direct attention to any mechanical want, to find it supplied in a very short time in a manner which leaves very little to be desired. The chief cause of the excessive leakage has been, of course, the imperfection of the longitudinal valve, which, according to the designs of Clegg and Samuda, was made of a long strip of leather rivetted between iron plates; the manufacture of vulcanized india-rubber had not then arrived at any great perfection. Leather, as is well known, soon dries up, hardens, and becomes incapable of making a tight joint, unless it is kept under water or in pumps; in consequence, this valve never answered its purpose very well. We believe that the substitution of some soft preparation of india-rubber instead, would be attended with the best results; Clegg used a hinge-joint. We would suppose that a continuous rope as proposed by Pinkus, say 2 in. thick, made of this soft india-rubber, might easily be so arranged as to run over large grooved pulleys affixed to the piston rod within the tube, in such a way as to gently raise the rope from the groove in the top of the tube, while similar wheels attached to the piston carriage would press it down to its place after the piston had passed; the sides of the groove should be planed to "V" shape, like those in the bed of a planing machine: any of our india-rubber factories would soon supply such a rope, soft, elastic, and unpermeable. Did this plan fail, plenty of others are open for our adoption. It would indeed be a disgrace to our engineering talents if we failed to make such a valve tight enough to fulfil every practical purpose.

The second objection, the difficulty of stoping the train exactly when desired, would be easily overcome on a railway filled with such an efficient system of signals as the Metropolitan—it would be a mere matter of working detail. A suitable valve being fitted at each station, in such a manner that when it was closed all communication with the pumping engine and that part of the tube between the valve and the piston attached to the train would be cut off, it would be only necessary for an attendant, informed by signal of the exact position of the train, to close the valve, when the further progress of the travelling piston would quickly destroy the vacuum before it, and consequently permit the train to be brought to rest; when it was again necessary to proceed, opening the valve would again establish a vacuum, when the train would go on as before. The persons in charge of the pumping engines, acting on the information derived from their pressure gauges, would, of course, slow or stop their engines while the train was at rest. We believe that by such an arrangement the utmost regularity and ease of management—the distinguishing advantage of the locomotive system—could be imparted to the atmospheric.

The question of speed and cost do not present many difficulties. A tube, 3 ft. 6 in. diameter, with pumping engines, &c., could, we believe, be put down for about £600 per mile of single line—a very trifling sum in comparison with the cost per mile of the Metropolitan Railway, and amounting even in the total to a comparatively small sum, as the railway is so short; such a tube, with a 7 lb. vacuum, would give a tractive force sufficient to propel a train of 250 tons at 30 miles an hour on a level, but half that pressure would suffice for ordinary traffic, railway leakage to a minimum. The duration of the permanent way, then, freed from the destructive action of a heavy locomotive, would be more than trebled; we have seen 50 lb. rails which had been in use on the Kingstown and Dalkey line for ten years, under half-hour trains, nearly as perfect as when first put down.

Engineers would do well to consider the matter. We believe that they will find a wide field for their talents: the ground is new and almost untrodden. All this considered, we can scarcely avoid the conclusion that, utterly unsuitable as it is for ordinary railways, no mode of propulsion can be devised more capable of suiting the wants and requirements of Metropolitan railways than the atmospheric system.

REVIEW.

The Working of the Steam Engine explained by the use of the Indicator; *or, an Exposition of the Best Means of producing the Greatest Impulsive Effect from a Given Quantity of Fuel: with a Description of the Mode of Expanding Steam, and the Compounding of Engines.* By Joseph Hopkinson. Illustrated with Engravings and Diagrams. 4th edition, enlarged and improved. London: John Weale, High Holborn. 1863.

Mr. Fairbairn, in his "Useful Information for Engineers," estimated that in 1859 the extent of steam power used in Great Britain was about 11,000,000 horses' power.* The same authority believes that this has increased within the last three years to upwards of 12,000,000 horses' power, in the British Isles alone. The quantity of coal consumed in raising this enormous load of 9,733,214,500 tons one foot high in an hour, he estimates at nearly 25,000 tons, assuming that the average consumption of each of the 11,000,000 horses' power, per hour, is equal to 5 lbs. of coal.

Leaving theoretical problems as to the purely dynamic properties of heat out of the present question, it is well known that engines could be designed and made to work with a consumption of coal, per hour, not much above one quarter of the above amount per horse power. If a man that can make two blades of grass grow where only one grew before, be entitled to the gratitude of his fellow men, how much more must he be recognized as a benefactor who can make a pound of coal give the power of two horses where it formerly only gave one? We would not be supposed as saying that the author of the work we are examining is entitled to national gratitude; his book is deficient and faulty in many ways; but, nevertheless, we consider that it is, in several respects, admirably suited to the comprehensions of unprofessional users of steam power and their engine-men. To such it must be very valuable. We have little hesitation in stating our belief that such persons, of common abilities, after attentively reading this book, ought to be able to get almost as much work out of their engines, with the least expenditure of fuel, as is permissible by the original construction of the apparatus. Those who are acquainted by experience with the often lamentable ignorance of men in charge of steam machinery in the manufacturing districts of England, will forget the want of scientific precision, good taste, and grammatical knowledge of this book on the indicator, and, while only looking to its sterling practical qualities, will hail any means—however otherwise deficient—by which an ordinary engine-man can have some control over the consumption of fuel of his engine, and an unprofessional user of steam power some control over his engine-man. With these excuses, both for Mr. Hopkinson and for ourselves, we will now begin our examination of his book. About fifty pages of this work are given to general elementary directions for the use of the indicator; there are then some thirty pages on most of the different kinds of steam valves, which are followed by a large number, nearly ninety, of indicator diagrams, very well chosen, in order to illustrate the principles of valve-setting. Some observations on working steam expansively and on the compounding of engines then follow. Perhaps the best part of the book is "On the Management of the Steam Engine and Boiler." Lastly, there is a voluminous appendix of tables, "calculated to be of service to engineers."

We find that Mr. Hopkinson, on the title-page of his book, quotes the simile, no less ingenious than true, that "What the stethoscope is to the physician, the indicator is to the skilful engineer—revealing the recent workings of the inner system, and detecting minute derangements in parts obscurely *situate* (sic)." It would have been more graceful in Mr. Hopkinson to have acknowledged the source of the above quotation, because a reader is naturally led to suppose that it is an extract from his own book. The passage quoted, however, is to be found in a small work by Professor T. J. Main and Mr. Thomas Brown.*

Mr. Hopkinson writes "obscurely *situate*"; but this alteration in spelling the adjective without a *d*, does not give him an original claim to this very good motto for a work on the indicator.

The history of the instrument in the opening pages, seems to us to be stated rather incompletely. Mr. Farey, the distinguished engineer and scientific writer, in his evidence before the Select Committee of the House of Commons, formed in 1829, to hear witnesses on the law relative to patents for inventions, gave the following account of the origin of the indicator. Mr. Farey cited this case, amongst others, in order to illustrate the importance of a good patent law in bringing forward and making public inventions that would otherwise be kept secret, and perhaps eventually be lost—"Many years ago, Mr. Watt invented and applied a small instrument, which he called an INDICATOR, to his steam engine; it indicates what extent of plenum and vacuum is alternately formed within the cylinder to impel the piston when the engine is at work. It is of very important use in giving engine-makers true knowledge how to make good engines; and it was of very great use to the inventor, *just as a hydrometer is to a distiller*. He kept it a profound secret for many years; and in 1814, when he published an account of his other inventions, he gave only an imperfect description of a part of this one, without any list of parts which are essential to the successful use. A complete instrument afterwards fell into my hands in Russia, where it had been made by some of the people sent out from this country with Mr. Watt's steam engines. On my return to England, I made one, and also showed several other engineers how to make such for themselves, and, since that time, every one of those persons has very greatly improved his practice by the light it has enabled him to throw upon an obscure part of the operation of steam in an engine. One person who had made an indicator from a sketch that I drew for him, has since printed a description of it in a public journal."

In the chapter on "How to affix and use the Indicator," we are directed (page 14), to mark the atmospheric line *first* and *before* the diagram is taken. Mr. Hopkinson says:—"During these motions the pencil will make a line on the paper round the cylinder. This line is called the atmospheric line. *When that line is well-defined,* open the tap gently, so as to make a connection between the cylinder of the engine and the cylinder of the indicator." Now, in our experience in taking indicator diagrams, we always thought that the atmospheric line should not be taken before the rest of the diagram had been completed. A little reflection will show us to be right; as the heat of the steam will evidently exert an influence on the relative positions of the parts, on the spring itself, &c., and, therefore, on the position of the line which affords the fundamental basis from which the entire result of the diagram is to be calculated. We believe that it is also better to mark the scale of pounds on the paper diagram *before* taking it off the barrel.

The chapter on "Nominal and Indicated Horse-power," is clearly and intelligibly written, as far as it goes; but it is somewhat incomplete, as Mr. Hopkinson gives the rules that are probably only used in his own locality for estimating the horse-power of steam engines. He states (page 32), that the purchaser of a condensing engine should have 22 square inches area of piston, for each "nominal horse power, whatever the speed or pressure." At page 33, it is stated that, "Eleven square inches area of piston is one nominal horse power of a high-pressure engine." Mr. Hopkinson does not say one word about the bewildering number of rules for nominal or commercial horse-power, forming quite an anomaly in steam-engineering. Most of these rules have been collected by Mr. D. K. Clark, in his article "Steam Engine," in the last edition of the "Encyclopædia Britannica," vol. 20, page 602. We will extract the following from this article for the benefit of our readers and of Mr. Hopkinson:—"*Boulton and Watt's Rule* assumes speed of piston to be 128 ft. per minute, multiplied by the cube root of the length of the stroke in feet; and the mean effective pressure to be 7 lb. per square inch. Then, nominal horse-power

$$= \frac{\sqrt[3]{\text{stroke in feet} \times \text{diameter}^2 \text{ in inches}}}{60}$$

---

*Steam-engines employed.	Horses' Power.	
	Nominal.	Indicated.
In Mining and Metal Manufactures	450,000	1,350,000
,, Manufactories	1,350,000	4,050,000
,, Steam Navigation	850,000	2,550,000
,, Locomotion	1,000,000	3,000,000
Total	3,650,000	10,950,000

* The Indicator and Dynamometer with their Practical Applications to the Steam Engine. By Thomas J. Main, M.A., F.R.A.S, and Thomas Brown, Chief Engineer, R.N. London: Longman, Brown, and Co., Paternoster-row.

This rule is much in use in the south of England, and to some extent in Manchester.

Manchester Rule.—The common rule is to allow 23 square inches of piston per nominal horse-power, or nominal horse-power

$$= \frac{\text{area of piston in inches.}}{23}$$

Occasionally 30 is used for the divisor.

Leeds Rule.—This rule is taken in terms of circular inches of piston, or the simple square of the diameter, allowing 30 per nominal horse-power; thus, nominal horse-power

$$= \frac{\text{diameter}^2 \text{ in inches.}}{30}$$

This is, practically, almost identical with the Manchester rule, as 30 circular inches are equal to 24 square inches.

For non-condensing engines, the usual rules are as follows:—

Manchester Rule.—Ten square inches of piston are allowed per nominal horse-power; or, nominal horse-power

$$= \frac{\text{area of piston in inches.}}{10}$$

Leeds Rule.—Sixteen circular inches are allowed; thus, nominal horse-power

$$= \frac{\text{diameter}^2 \text{ in inches.}}{16}$$

Glasgow Rule.—Square the diameter of piston in inches, and point off the unit figure. The result is the nominal horse-power. This is the same in form as the Manchester rule, as it is essentially a process of division by 10. The Leeds rule is more liberal than the other, as 16 circular inches are equal to about 13 square inches. For compound engines, having both non-condensing and condensing cylinders, it is the custom in Leeds to throw in the small or non-condensing cylinder, taking no account of it, and to rule from the condensing cylinder only."

Mr. Hopkinson is incorrect in asserting (page 37) that "the merit of the discovery (of the expansion of steam) is due to Hornblower, who, in 1781, obtained a patent for the invention." In 1792 Hornblower applied to Parliament for an Act to prolong the term of his patent of 1781, but the bill was thrown out through the opposition of Messrs. Boulton and Watt, on the plea that Hornblower's engine was a plagiarism of Watt's patent of 1769, extended in 1775 for the term of 25 years from 1775. Watt, in a letter he wrote to Dr. Small, of Birmingham, in 1769, describes the principle of expansion as capable of doubling the effect of the steam. The following is the passage of the letter:—"Open one of the steam-valves, and admit steam until one-fourth of the distance between it and the next valve is filled with steam; shut the valve, the steam will continue to expand, and to pass round the wheel with a diminishing power ending in one-fourth of its first exertion. The sum of this series you will find greater than one-half, though only one-fourth steam was used." Watt used it on an engine at Soho in 1776, and in 1778 he applied it to an engine for raising water at Shadwell. Mr. Hopkinson was probably led into this mistake from the fact of Watt's taking out a patent in 1782, in which the principle of expansion was the main feature, this patent being thus about one year subsequent to the patent of Hornblower. The principle, however, was not completely embodied in Watt's patent of 1769. The discovery of the principle of expansion of steam is said to be another instance of the result of a fortuitous observation made while endeavouring to attain a different object. Watt, wishing to moderate the impulse of the piston of the single acting engine towards the end of the stroke, caused the valves to shut previously to the end of the course of the piston; the realization of increased effect was a result that he had not calculated upon, but which he at once took full advantage of by means of his peculiarly strong powers of observation. By thus setting the catch-pins of his single acting engine, Watt merely wished to obtain somewhat the same effect that we call "cushioning" on a high-pressure engine; arrived at by means of the lead of the slide valve.

It is stated (page 41) that further improvements (in Cornwall pumping engines) have taken place, proving the advantage of high-pressure steam and expansion over that of low-pressure steam and no expansion. It happens, however, that the duty of the Cornwall engines has within late years rather diminished than increased; railways having made the coal cheaper, they do not care so much about wasting it.

We also rather differ with the author in his assertion that great economy has been effected in locomotives by the use of expansion. It is notorious that there is a very large field in that direction still unexplored by railway engineers; and we believe the main reason to be that neither the indicator of Mr. Hopkinson, nor those of Messrs. Macnaught, Gooch, or Bourdon, have been able to take really true diagrams off a locomotive cylinder—we mean diagrams that could be implicitly relied upon.

Mr. Hopkinson appears to us to make rather a cool statement in referring to the use of expansion in marine engines* (page 43):—"Since former editions of this work appeared, marine engineers have begun to act on the principles recommended in the foregoing, and the results have been most satisfactory" (!). We wonder whether, for instance, Mr. Edward Humphreys, of Deptford, regards himself as one of Mr. Hopkinson's pupils in steam engineering.

At page 45 it is stated that the average friction of stationary engines with the shafting is 3 lb. to the square inch of piston. A friction diagram, taken from the top of a condensing engine cylinder is also given at page 45, and the average pressure is 3·5 lb. to the square inch upon the piston. This appears to us be a large average. The size of the engine, &c., is not stated. Small engines have, of course, more friction in proportion than large ones. Again, when the load is on, there will be additional friction; and this friction will be more or less according to the qualities of the oils used for the machinery, &c. In addition to this, the air pump of a condensing engine will have more work when the load is on. These little matters, however, seem to be below the notice of Mr. Hopkinson. This chapter, of three pages, on taking a friction diagram, altogether appears to us to be too short. The book professes to instruct unscientific and unprofessional men, but the author has quite neglected to properly caution an engine-man taking a friction diagram for the first time. It is rather a delicate operation to give an engine steam enough to drive it without its load; an incautious experimenter could very easily break down an engine in this way.

The following is an excellent expression of opinion that is worth quoting, and it is one in which we entirely agree. In describing a well managed cotton mill, he says:—"The engine is indicated every day, and the diagram put into a book for reference; so that, should any alteration take place in the working of the engine or the machinery, or even an increase of friction from bad oil or other causes, it is easily detected. It is found out before it is visible in the amount of fuel wasted; instead of the fuel being lost, the defect is remedied. This is as it ought to be; and were the practice followed up in all cases with the same exactness at the time of starting and stopping the engines, it would be productive of great advantage to owners, and save engineers many a late hour now spent in the examination of engines after the work of others has terminated. It is as necessary for an engineer to have the working interior of his engine laid open before him in a diagram taken every day, as it is for him to see the exterior. Such a practice, if regularly attended to, would save many 'break-downs' and expensive repairs, besides making the mind familiar with the internal working of the engine. Any alterations in the working of his engine would cause the engineer to reason out the various changes that take place from day to day. The advantage would become so apparent that he would continue to make improvements in the management and working of his engine, to economize the fuel and regulate the speed. These important benefits could all be attained with less labour than is entailed by the hap-hazard and guess-work system." By "engineer" Mr. Hopkinson of course means engine-man. It has often struck us as a great anomaly to call an engine-driver an "engineer"—a man who is often not even a workman, much less a man of science and an artist. All three qualifications are required of *an engineer.* He must be an artist, to invent and beautify; a man of science, to correct the conceptions of the artist; and, last of all, a workman, to reduce his designs to practice. It seems to us absurd to call a man requiring so many qualifications by the same name as another who is little removed above the class of a hand labourer.

At page 60, are some excellent practical directions for "lapping the thoroughfares," when the valve chest is too short, and lap cannot be added to the valve. Such passages would go far to redeem a much worse book. At page 64, again, are some sensible observations about agricultural steam engines, which might be useful in some quarters. From what we have seen, we believe that the makers of portable engines, as a class, very much neglect the indicator. The author recommends *his* revolving expansion valve, page 84, for use in locomotives, stating as a reason that the pressure on the back of the ordinary three-port slide valve *is the full boiler pressure throughout the working.* We beg leave to differ from this opinion. There is little doubt that a film of steam interposes itself between the valve face and steam port of a high-pressure cylinder. A practical proof that these valves are *not* weighted with the full pressure due to the area of their backs, is, that numbers of these valves have been working for years without their faces being at all ground away. This could not, of course, happen if they were held down with a pressure, say, of 100lbs. to the square inch.

As an illustration that we were not exaggerating the necessity of either the schoolmaster or the indicator, or rather both, being sent abroad in the manufacturing districts, we will quote the following:—"The *maker* of the Gateshead (on the Tyne) engine prided himself upon the superiority of this engine over others, from the great noise the steam made in the exhaust side. As a proof that it was a good one, several people were called in to hear the good vacuum the engine was making. The noise produced by the exhaust was similar to the noise made by the escaping steam at the top of a locomotive engine chimney!"

---

* Expanded steam was used in marine engines as early as 1819, as will be seen in our volume for 1829.

Further on, there is an excellent suggestion to remedy the condenser being made too small and not in proportion to the size of the cylinder :—" When this is the case, the condensing water should be introduced to the steam in the exhaust pipe before it enters the condenser. The water traversing along with steam into the condenser tends to condense the latter quicker and better."

Mr. Hopkinson states (page 108) that "a mistaken opinion exists amongst engineers as to the cause of the irregularity which the diagram exhibits. Many suppose that the irregularity of the figure is caused by the irregularity of action in the indicator, arising from a want of correctness in the working parts, or from the spring of the instrument being too weak." There is no doubt that, in this case, this might have been " the result of the valve (of a low-pressure engine) having too much lead, and of its opening too quickly, so that the rush of the steam struck the piston of the engine with great force in the same way as steam is applied to the steam hammer." But it is also evident that, at high speeds, both the momentum of the steam itself, the momentum of the spring, and of the other reciprocating parts of the ordinary indicator, must influence the diagram of an engine working at a high pressure and speed. The piston of the indicator being thrown up by the momentum of the entering steam so much above the height due to the real pressure of the steam in the cylinder, that the spring thus continues to oscillate during the remainder of the strike, and the result is a jumping, serrated, zigzag diagram. Mr. Hopkinson does not deny the percussive action of steam, as will be seen in the above passage. It will be observed that amongst the very interesting 88 indicators diagrams given by Mr. Hopkinson, only three are taken from high-pressure cylinders, properly so called ; we mean leaving out those taken from the high-pressure cylinders of compound engines. The old remedy for this evil was to make the piston of the indicator somewhat tighter than usual, but this was naturally at the expense of the sensitiveness of the instrument, and of a consequent inaccuracy of the diagram. A small counterspring has, we believe, been sometimes applied.

Another way of diminishing, or even of altogether preventing the vibration of the indicator piston, caused by the percussive action of the steam on the spring driving it up far above the point corresponding to the boiler-pressure, is by throttling the passage of the steam through the cock; the effect produced is also evidently at the expense of the sensitiveness of the indicator and of the consequent accuracy of the diagram. There are other causes besides this that exercise a deleterious influence on the diagram—influences, however, that are not alluded to by Mr. Hopkinson.

At page 165 Mr. Hopkinson says, very truly, that " an engineer, when indicating his engine, to ascertain its real state, should take a double diagram, by which means he will see the slightest difference that may exist in the working, from any unequal admission of steam to the upper and the wider side of the piston." We would go further than this, and assert that when merely the horse-power of an engine is required with any accuracy, a double diagram should always be taken, and the average result would afford the true mean pressure of the steam on the piston. The obliquity of the connecting rod, giving a different diagram for each side of the piston, besides some other influences, are reasons why a double diagram should nearly always be taken.

At pages 108 and 199 Mr. Hopkinson brings certain charges against the McNaught indicator in general, and more especially against the small size of indicator used by the travelling inspectors of the Manchester Boiler Association. We fully agree with Mr. Hopkinson that the larger an indicator the better, other things being equal. There are several reasons, to which we will allude on a future occasion, why a small indicator should be more or less untrustworthy. The original indicators of Boulton and Watt were all of a large size, and were made with a large powerful spring, while the stroke of the piston was much shorter than in the ordinary indicator as made at present. Speaking further about the McNaught indicator, Mr. Hopkinson says :—" This latter description of indicator is not sensitive enough to show the true action of the steam upon the piston of the engine, because the pencil-holder, with the pencil in the position described, acts as a lever with a motion opposed to the motion of the piston, and adds additional friction, preventing a true tracing on the barrel of the indicator." No doubt, under certain circumstances, there is some truth in these strictures. Taking the indicator cylinder as the axis of the diagram barrel, seems also a more mechanical arrangement. The McNaught form, however, is cooler to handle. We have heard, from a source that ought to be reliable, that the late Mr. McNaught, of Glasgow, made several indicators of the form now adopted and manufactured by Mr. Hopkinson. This was in 1826.

The author remarks, page 193, thus :— " Engines for corn mills should traverse at a quicker rate than most other engines, because, where the speed of the work driven—millstones, for example—is great, the speed of the engine should be greater ; if not, there will be what is termed a 'back lash,' and great wear and tear is the result under circumstances of that nature."

We must now notice the peculiar way adopted by Mr. Hopkinson in ascertaining the power of any condensing engine, the steam-line of which expands *below* the atmospheric or datum line. The method he uses does *not* give a really wrong result, when it is wished to ascertain the *gross power* of an engine by means of the indicator ; if, however, it be desired to find *separately* the respective values of the *steam* and *vacuum* pressures, his method is decidedly incorrect. The universal way of ascertaining the mean steam pressure on the piston throughout the stroke, by means of—1st, the steam, and 2nd, the exhaust curve of any indicator diagram, is simply to at once take the mean distance between these two curves. To find the average pressure on the piston throughout the stroke, or to " sum up " the diagram, it is divided at right angles to the atmospheric line in any convenient number of equal parts. The number of pounds between these spaces included between the steam and vacum lines are then measured off by means of the scale belonging to the indicator. The total result is then divided by the number of columns, and the gross average pressure on the piston during the up and down stroke is thus obtained. This is the method used by Mr. Hopkinson for his high-pressure engine curves ; it is also the method that is always adopted by the steam department of the Admiralty and the principal firms in the kingdom ; the little book sent out by Mr. McNaught with his indicators also advocates no other plan.*

In dealing, however, with the diagrams of condensing engines, Mr. Hopkinson adopts a peculiar method. Instead of *at once* measuring right across the diagram, he separately measures the ordinates of the steam and vacuum curves, from the atmospheric line as a basis. The evident result of this plan is, that if he merely wishes to obtain the *gross* pressure on the piston throughout the stroke, he does this at the expense of double work. If he wishes to find, *separately*, the *exact value* to be given to the steam and vacuum pressures, he obtains an inaccurate result. It will be at once seen, on reflection, that we are right. In any properly constructed condensing engine, the steam line of the diagram expands *below* the atmospheric line. At the beginning of the stroke it is *above* the line, and further on it runs *below* the atmospheric line. In adding up the steam pressures, Mr. Hopkinson only notices the *plus* pressures *above* the atmospheric line, while he neglects the *minus* steam pressures *below* the atmospheric line. In adding up the vacuum pressures, instead of taking the complete vacuum up to the atmospheric line, he measures the ordinates between the steam line (that happen to be below the atmospheric line) and the vacuum or exhaust line. It will be at once perceived that the steam pressure is exaggerated by only taking the *plus* pressures into account, while the vacuum pressures are detracted from by not measuring them up to the atmospheric line. The *total* amount comes *right* at last ; but the *separate* values of the steam and vacuum pressures are *wrong*. Mr. Hopkinson says, in the preface, page iv. :—"Although the mere theorist or scientific literary writer may object to the plain and simple manner in which the different topics descanted on is (*sic*) treated, the author is assured, from the difficulties which in the early periods of his experience he himself had to contend with and overcome, that his plan of procedure is the best that he could possibly have adopted for the accomplishment of his main object in undertaking the work—the instruction of the practical *working* engineer." We suppose Mr. Hopkinson will put us down as " mere theorists " for making these objections. However that may be, we look upon this book as a very valuable work in many respects, and we should be only too happy to receive any valid excuse. But it happens that there is a simple plan by which the most ignorant fireman, totally unconscious of the deep mysteries of *plus* and *minus*, can take the separate values of the steam and vacuum pressures, of an indicator diagram. It is one often employed in the steam department of the Admiralty. The atmospheric line is taken as equal to 15 lb. ; and from this line, as a point of departure, fifteen other lines are marked by the scale, thus coming below the vacuum line of the engine up to the true vacuum line of a perfect exhaust. The *lowest line* is then taken as the *zero* or *datum* line, and the *actual* pressures (not the relative pressures as compared with the atmosphere) of both the steam and vacuum lines can thus be obtained. The difference between these two pressures gives the gross or actual pressure on the piston.

To engineers, *not* enginemen, having often to calculate the actual horse-power of steam engines from indicator diagrams, we would recommend the use of a very handy book of tables of logarithms compiled for this purpose by Mr. James Overend.* It is simply a compilation of four logarithmic tables—the first giving the logarithms of the areas of cylinders from a diameter of 25 in. to 99¾ in. ; the second contains the logarithms of the pressure per square inch on the piston from 10lb. to 91lb., and of the revolutions per minute from 10 to 91 ; and the third, the revolutions per 24 hours corresponding to these revolutions per minute. The fourth table is one of the common logarithms of numbers from 1 to 1,500. These tables must be delightfully convenient to a marine engineer having to calculate a diagram under the burning sun of the tropics, superadded, perhaps, to the heat of the engine room. It is evident that there must be a saving of, at least, three-fourths of the present amount of labour.

* Tables for Calculating the Power of Steam Engines, from the Diagrams furnished by McNaught's Indicator. By James Overend. London : Waterlow and Sons.

We will resume our notice of Mr. Hopkinson's book in a future number.

INSTITUTION OF CIVIL EMGINEERS.

At the meeting of the Institution, on March 31, 1863—John Fowler, Esq., Vice-President, in the chair—the Paper read was on "Structures in the Sea, without Coffer Dams; with a Description of the Works of the new Albert Harbours at Greenock," by Mr. D. Miller.

It was stated that the immediate object of this Paper was to treat of the various methods of constructing the foundations of quays, walls, piers, or breakwaters, for the formation of docks and harbours in deep water; and to describe works of this kind which had been carried out on principles different to those usually practised, and to point out the further application of those principles to other structures of a similar nature.

The plans which had chiefly prevailed were, founding on piling carried up to about the level of low water, constructing within caissons or coffer dams, or building under water by means of diving apparatus. Instances of the failure of the first of these methods, which was believed to be inapplicable where there were marine worms, were given. The second was most effectual, but was generally expensive, and often attended with danger. The last was also costly, besides being subject to delay in the progress of the works. In bridge building, of late years, the plan of forming enclosures of close piling of the shape of the pier, and filling in with hydraulic concrete, had been pursued by French engineers; and the substitution of iron for perishable timber piling, in the construction on this plan of the piers of the Chelsea and Westminster bridges, by Mr. Page (M.Inst.C.E.), was considered to be a successful departure from stereotyped rules.

Although the value of béton or hydraulic concrete was now appreciated in this country as a substitute for masonry, and had been employed in some important works; yet its use was chiefly confined to forming a homogeneous and monolithic bearing stratum for foundations, and not, properly speaking, as a constructive material. The modes in which concrete had been applied for constructive purposes—were building it dry in a mass, and allowing it to set before being placed in the work, as had been adopted in the construction of the walls of the Victoria and of the London Docks; preparing it first in blocks, and allowing it to harden before being used, as employed at the Dover Breakwater, and for the new sea forts at Portsmouth and Plymouth; and depositing it in a liquid state, and allowing it to set under water, as practised at the Government Graving Docks at Toulon. The facilities for making béton which had the invaluable property of setting under water, and of thus forming an artificial rock or stone, were very great; as it might be made either from the naturally hydraulic lines, the artificially hydraulic lines, or cement, or from rich or non-hydraulic lines, rendered hydraulic by the admixture of other substances such as Puzzolana, minion, or iron mine-dust. Various examples were adduced of the application of concrete, on a large scale, prepared from these different materials, especially at the Mole of Algiers, at the breakwater at Marseilles, and at other French ports, as well as in the Pont d'Alma over the Seine, in which case both the arches and the piers were formed of rubble concrete.

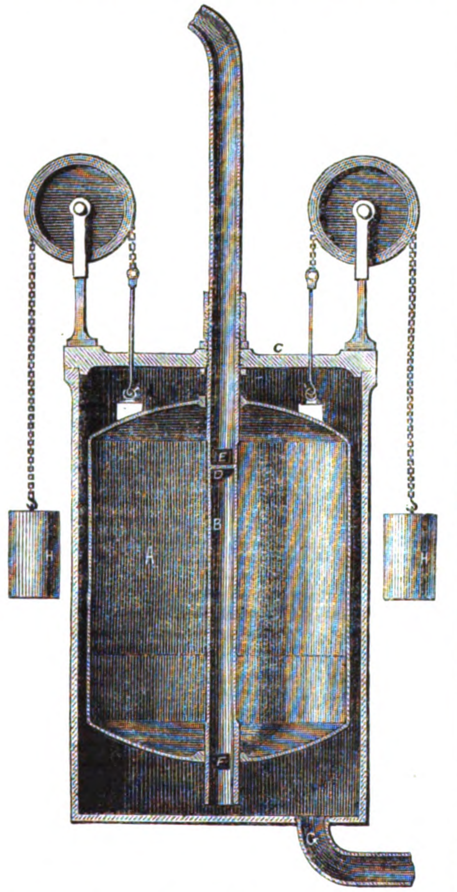
As Engineers-in-chief for the new harbour works for the port of Greenock, the author and his partner, Mr. Bell, had an opportunity of introducing a system of constructing sea walls and quays in deep water, without the aid of copper dams, diving apparatus, or other means equally expensive. These works were situated on the west side of the town, and had been projected almost entirely beyond the high-water line into the sea. The outer pier would ultimately be upwards of 3,000 ft. in length and 60 ft. wide at top, with quays on both sides. Within this there would be space for two harbours, each 1,000 ft. in length, 15 ft. deep at low water, and 25 ft. at high water, with entrances 100 ft. wide, and ample room for the construction of graving docks, for the storing of timber, and for the erection of sheds. At present it was only proposed to erect about one-half of the sea pier, and to form one harbour or tidal dock. In the design of these works, it was suggested that the walls, under low water should consist of a combination of cast-iron guide piles in the front, with a continuous stone facing, slid down over and enclosing these piles, timber-bearing piles being used in the body of the walls where reqnired, and concrete backing being deposited in a soft state; and that the upper part of the walls should be built of masonry in the usual manner. The first operation, when the water was not sufficiently deep, was to dredge two parallel trenches to the required depth, 17 ft. below low water, for the foundations. A staging of timber piles was afterwards erected in the line of the pier over its whole breadth, or carrying the tramways, travelling cranes, and piling engines. The cast-iron guide piles were then driven from the staging, with great precision, 7 ft. apart in the line of the face of each quay wall. These piles were driven until their heads were near to the low water line, by pile engines furnished with long arms projecting downwards, strongly stayed by diagonals, and forming a trough into which the pile was placed, and from which it was shot, like an arrow from a cross-bow. The piles were connected at the top transversely by wrought-iron tie-rods stretching through the pier. When the piling was driven, a bed of hydraulic concrete, 3 ft. thick, and 20 ft. wide, was deposited in the trenches to form a base for the wall, and to give a large bearing surface. Into the grooves formed by the flanges of the iron piles, large granite slabs, from the Ross of Mull, from 18 in. to 2 ft. thick, were slipped, the bottom one resting on the concrete base, and on a projecting web cast on the piles. This constituted the face of the wall, and in each compartment betwween the piles, 16 ft. in height and 7 ft. in width, there were only three stones. Behind this facing hydraulic concrete was lowered under low water in large boxes having moveable bottoms, and was discharged in mass to form the body of the wall. To confine this at the back before it had set, loose rubble stones were deposited. The hearting of the pier consisted of hard till, stones, and granite, up to the level of low water. When the whole of this mass was consolidated, the heads of the iron piles and the granite facing blocks were capped by a granite blocking or string-course, and the upper portion of the walls was built in freestone, ashlar, and rubble. The remainder of the hearting between the walls was then filled in, and the whole finished with a granite coping and causeway. The walls were 33 ft. in height from the foundations, 11½ ft. thick at the concrete base, diminished to 5 ft. at the top. In the part of the work already executed, the outer flange of the iron piles was exposed to the action of the salt water. In future it was intended to reverse this plan, and to make grooves in the stone facing, so that it should overlap the iron piles, filling in the groves from the top with cement. When the whole extent of the seaward pier was completed, the interior operations for the harbour would be proceeded with; this pier serving as the principal coffer dam, and a short dam, about 100 ft. in length, closing the entrance. It was stated that this mode of constructing walls in deep water without coffer dams had been most successful, and that a sea-pier of great solidity and durability had been formed in deep water at a comparatively moderate cost. The works of the Albert Harbour were being executed under the superintendence of Mr. John Thomson, as Resident Engineer, by Messrs. W. and J. York, contractors.

The application of this system to the construction of breakwaters and harbours of refuge, was then noticed, reference being first made to the principal modes of construction hitherto adopted, and to the peculiar phenomena by which such structures were affected. The usual method of forming breakwaters was by the "pierre perdue," or long-slope system, as carried out at Plymouth, Cherbourg, and Holyhead. Where stone was not abundant, a vertical wall was built from the bottom by means of diving apparatus, of which the breakwater at Dover, now in course of construction, was the most prominent example. Besides these systems, which might be taken as the extremes, an intermediate form of section, combining both, that was to say, a rubble mound to a certain depth under low water, and a vertical wall above, had been carried out at Alderney. From an examination of the general principles which affected breakwaters, and the modes of construction usually adopted, the conclusion arrived at was, that the vertical system was that which best resisted, or rather averted, the destructive action of the sea, and required the smallest amount of material. Both the long-slope and the vertical systems, as at present carried out, were expensive, from the quantity of material used in the one case, and the costliness of the material and the mode of construction in the other. The former might be characterized as involving the maximum in quantity, and the minimum in cost of material; the latter, on the contrary, the minimum in quantity, and the maximum in cost of material. The object sought to be attained in the new system was to effect a minimum, as far as possible, both in the quantity and in the cost of the material. Breakwaters might be thus constructed, either wholly vertical from the bottom, or partially vertical, springing from a rubble mound. The principal feature of the new plan was a framework of iron piles, or standards, and ties, which would serve during the construction as the staging, and would afterwards form an essential portion of the structure, by binding together a strong casing of stone, or other sufficiently durable material, which would enclose and form the facing of the breakwater, the interior being filled up with loose rubble, cemented into a solid mass by liquid concrete. As soon as a pair of piles transversely had been fixed, rubble would be deposited up to, say, 18 ft. under low water. Strong casing blocks, either of stone or of béton, made to enclose the iron standards, would then be lowered, the blocks being locked or arched into each other, so as to resist pressure from behind, and made to break bond, if thought desirable. The hearting of the work would be proceeded with simultaneously with the building of the casing, and would consist of rubble in the centre, and of hydraulic concrete behind the stone casing. It was believed that such a structure could be erected in a depth of 6 fathoms, with a range of tide of 15 ft., for £190 per lineal yard without a parapet, and at £200 per lineal yard including a parapet. The economy of this system would arise from the smallness in quantity and the cheapness of the bulk of the material. It would also possess the advantage of rapid execution, as the mass of the material could be deposited without any tedious operation being necessary, over a great length of the work at one time.

The author was of opinion that the system which had been described admitted of being applied for the construction of the works under low-water of marine fortifications, as well as of breakwaters, piers, quay-walls, lighthouses, and other similar structures. He considered that, although the mode of constructing any engineering work must be determined greatly by local circumstances, the system presented the following advantages—great economy, combined with strength and durability; facility and rapidity of execution; and adaptability to situations where the present modes of construction would be inapplicable.

STEAM TRAPS.

The following is a description of a steam trap, the invention of Mr. E. A. Pontifex, of Shoe-lane, London. This kind of apparatus for facilitating the escape of condensed steam, is applicable to any kind of steam machinery from which it may be desirable to draw off or remove water produced by the condensation of the steam. Instead of trapping the steam by means of a valve attached to a float as is now usually the case, and which float is exceedingly liable to stick and get out of order, the steam and water are allowed to enter a reciprocating rocking or moveable vessel or chamber which is properly balanced and is provided with valves or openings which are opened and closed as the vessel rises and falls. When the balanced vessel has received a given weight of water from the condensation of the steam, it will be carried down by its weight, and in so doing will uncover or open a valve at the bottom of the vessel, and allow the water to run out. The vessel thereby lightened will then be raised up again by the counterbalance weights to its original position, and will close the exit openings or valves until more water or condensed steam accumulates in the vessel, when the latter will descend again and allow the water to run out.



A variety of mechanical arrangements may be devised for effecting the object of the invention, but they will all be constructed on the principle of causing the weight of the water or condensed steam in the suspended or balanced vessel to overcome the counterbalance weight, and by carrying down the vessel to open or uncover a valve or valves or exit passages. For instance, the vessel may be suspended vertically by chains or cords passed over pulleys and counterbalanced by suitable weights attached to the other end of the chains.

In the accompanying drawing is shown one view of the arrangement of this apparatus. A is the balanced vessel, which is bored out truly so as to form a moderately steam-tight joint, and to enable the vessel or box A to slide with facility up and down on the inlet pipe B, which is screwed or otherwise rigidly secured to the plate C. This pipe B is stopped at D, and has outlet passages E, E, opposite each other so as to neutralize the friction, and to admit the water and steam into the balanced vessel A, which is free to slide on the pipe, B. F, F, are outlet ports or passages made opposite to each other near the lower end of the pipe B. G is a waste pipe for emptying the casing which encloses the balanced vessel A. H, H, are balance weights hooked on to the ends of the chains I, which pass over the pulleys J, J, and support the vessel A. The water and steam enter the apparatus down the pipe B, and pass through the ports E, E, into the balanced vessel A. As the water accumulates therein, its weight counterbalances the weights H, and ultimately overcomes them and causes the vessel to slide down the pipe B, and allow the contents of the balanced vessel A to have access to the outlet passages F, through which the water escapes from the vessel A and runs off by the waste-pipe G.

Another form of apparatus and mode of arranging the condensed steam-box A, is to balance this latter horizontally on a fixed hollow axis, through one end of which the water and steam are allowed to enter. When the equilibrium on the weight of the parts is destroyed, the condensed steam-box will oscillate on the hollow axis, and the water or condensed steam will pass out through an opening which the oscillation of the vessel will have uncovered on the other end of the axis.

MACHINERY BELTING.

Mr. M. T. Haines, who has already patented several plans for bands and straps, has lately patented additional improvements in the manufacture of driving bands or straps. In the

FIG. 1.

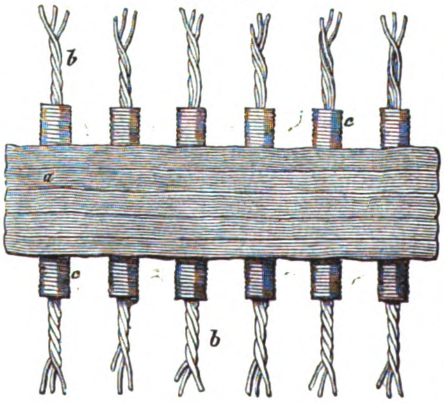


FIG. 2.

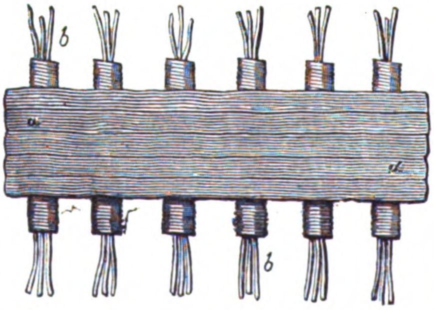

Specification of an Invention for which Provisional Protectional was granted to him on the 28th August, 1860 (No. 2078), was described the manufacturing driving straps of short strips of leather, hide, or other suitable material, cut to a width equal to the thickness and to a length equal to the width of the intended strap. The strips had holes formed through them, and were threaded side by side on lengths of wire rope, the wire rope thus running longitudinally of the strap. Now, according to the present invention, the lengths of wire are bound round rope with a helical coil of wire in such manner that the coils lie close up to one another before threading the strips of hide or other material upon them, or in place of employing wire rope thus bound round with wire, straight lengths of wire bound round with a helical coil of wire may be employed. Fig. 1 of the drawings hereunto annexed shows a driving strap composed of short strips *a*, *a*, of leather, cut to a length equal to its thickness the strips; have holes formed through them in order that they may be threaded on the lengths of wire rope *b*, which run lengthwise of the strap, each length of wire rope being bound round with a helical coil of wire *c*, as is shown, the wire and wire rope are both preferred to be of iron, but they may be of other metal. Fig. 2 shows a strap composed of short strips of leather *a*,*a*, threaded on straight lengths of wire *b* bound round with a helical coil, three lengths of wire being bound together by each coil, but this may be varied. According to this invention, driving straps are also formed by threading short strips of leather, or other material cut as above described, upon cords composed of raw hide cut into long thin strips; the strips are softened by soaking in water and are then twisted together into a cord, the cord may then be drawn through a circular die to render it smooth and even, or the short strips of leather may be threaded on cords composed of lengths of thin strips of raw hide and lengths of wire twisted together.

WATER VALVES.

The following is a description of a new kind of pump valve for large mining pumps. It is the invention of Mr. William Husband, of Hayle, Cornwall, and the object of the construction of this valve and seat is to obtain greater water or steam way than has hitherto been attained with the same lift of the valve off the seat, consequently to diminish the shock both in closing and opening the valve, and at the same time give greater freedom for the passage of liquid or fluid. It is also of almost equal importance that the weight of this valve may, in consequence of the reduced lift, be considerably diminished with a proportionate diminution of the motive power employed, and thereby, in steam engines, economizing fuel. On the seat of the valve box or nozzle is to be bolted an annular iron bed plate, having eight or other number of arms or supports extending obliquely upwards and inwards therefrom, for the purpose of sustaining an uppermost and an intermediate similar annular bed plate of the same diameter, or decreasing in diameter, according as the vertical section of the supporting arms to this point is parallel or decreasing in diameter. The bottom and top bed plates are each furnished with a ring of composition metal, wood, india-rubber, or other material, let into a channel cut around their surfaces, the surface of the rings being slightly raised above that of the plates. The central or intermediate annular plate has two of these gun metal or other rings let into its surface; namely, one at the upper and the other at the lower part thereof. There will thus be four rings of metal or other material in the seat, each of which serves for the bearing surface of corresponding rings of iron, which are formed by the lower surfaces of two dome-shaped caps or covers connected together by eight or other number of arms. The uppermost bed plate supports vertical gun metal bearings for the inner circumference of the upper dome, and to the lower part of the arms of the bed plate similar bearings are bolted in order that the connecting domes may be kept in a level or horizontal position during their rise and fall. The moveable portion of the valve is prevented from rising beyond a necessary height by means of a projecting flange at the top of the upper bearing surface, and a ring of vulcanized india-rubber or other material under the flange will obviate any shock or jar to the valve caused by the alternate ascent of the domes. Fig. 1 is a vertical section through the centre of the valve and seat; and fig. 2 is a plan view showing half the seat. A, A, represent the arms which unite the various valves B, B, which close on the seats C, C; the pressure of the water raising the valves from their seats and allowing it to flow towards the pump or the main as they may be used for suction or discharge. It will be observed that the arms A are cast or formed to unite the valves, inclined from a vertical plane, in such manner that the valve, when rising by the action of the water, will rotate, thereby ensuring an equal or level wearing of the beats and guides. It is preferred to give the upper part of the valve A the greatest proportional lifting area, in order to keep the centre of gravity of the valve low down and to prevent any tendency to cant to one side. This arrangement of areas is (according to the patentee) not always advisable, but in some cases may be modified, according as circumstances may require. The construction of the valve may be varied without departing from the principle of this invention by making it on the internal plan, that is to say, by making the seating approximate the form of a hollow cone and dropping the valve into it.

Fig I

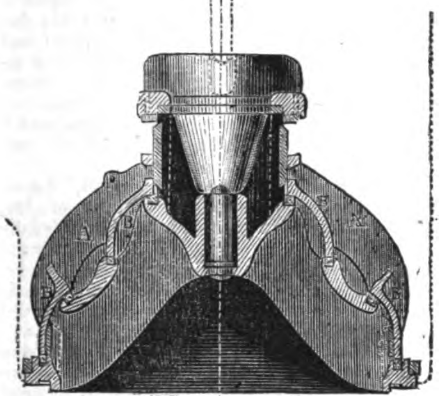

Fig 2.

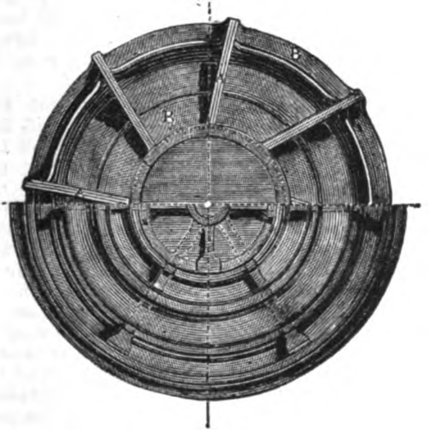
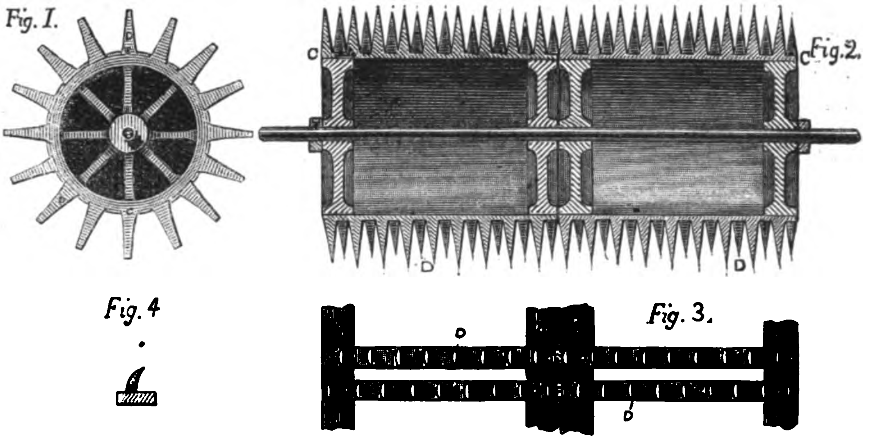


CLOD CRUSHERS.

Messrs. Joseph and Benjamin Harrison, of Otley, Yorkshire, have lately patented a description of clod crusher, which consists of two, three, four, or more drums, wheels, or discs, placed at intervals on a shaft, and a series of bars or lags with spikes cast or fixed on one side thereof, and which bars are fixed at small distances apart, or leaving spaces betwixt them across the edges of the drums with the spikes outward, thereby constituting a spiked skeleton roller or clod crusher. The bars are formed to fit into dovetail notches in the drums or discs, and arranged so that the spikes on one bar shall be intermediate to those on the adjoining bars in the line or direction of rotation.

MESSRS. HARRISONS' CLOD CRUSHERS



In the accompanying engravings, fig. 1 is an end view, and fig. 2 is a longitudinal section of the spiked roller or improved clod crusher.

The parts marked with the letter A are four cast-iron drums or wheels mounted on a wrought-iron shaft The rims of the drums have dovetailed notches or recesses formed so that the lags or bars C fit and are retained therein by the aid of a small bolt or pin *a*, passed through the lag and rim at each jointing. D are the spikes, which in this illustration are cast with the bars, but may be cast separate and fixed to wrought-iron bars, by having bolts or pins cast therein, or they may be cast on to the wrought-iron bars by having suitable holes first made in the bars, and the bars placed in the mould when casting the spikes, or both spikes and bars may be of wrought iron and rivetted or screwed together. The spikes are so placed on the bars, or the bars so arranged when fixed on the drums, that the spikes are intermediate to each other, as shown at fig. 3. Fig. 4 is a side view of a picker or spiked bar, to be applied to the clod crusher for picking out or removing from betwixt the spikes any clods, stones, weed, or other substance which may stick therein during the working or using of the same. It must now be understood that this roller or clod crusher is to be mounted or provided with suitable framing for removing it, such as in ordinary use with rollers or clod crushers, but which forms no part of this invention, and being well known it has not been thought necessary to describe or show by engravings.

It will be seen that the roller here shown is in two parts in length, thus forming two rollers on one shaft, both of which run loose, so as to give ease in turning at the ' headlands," or where required; and it will be evident they may be made in three or more parts if desirable, or in one length only, and either loose on or fixed to the shaft. For the moving of this roller on roads from field to field, and where the spikes are not required to operate on the ground, a pair of plain portable wheels of larger diameter than the spiked roller are applied or placed one on each end of the shaft, by which the roller is supported and the points of the spikes are kept clear of the ground.

THE STEERING OF LARGE SHIPS.

At the last general meeting of the Institute of Naval Architects, Mr. Nathaniel Barnaby read an able Paper " On the Steering of Ships, particularly large Ships-of-War." The following is an abstract of the Paper :—

Within the last twelve months the idea of employing the momentum of a ship of war as a means of injuring the enemy has gained ground, and nearly all the war-ships in course of construction in England and France have such a form of stem, and such increased strength of bow, as will allow them to be used as rams should the opportunity occur. The "Resistance" and "Defence," for example, have been shorn of those graceful appendages, the figure-head and knee, the stem has been made to fall back at the head, the bow has been built with extraordinary strength, and various other measures have been taken to make it possible to employ these ships in such a service. But it would be idle to suppose that they would able to avail themselves of the vast power of attack possessed by them in this respect with their present steerage power.

Let us see how the matter stands. Under favourable circumstances, the "Resistance" can turn completely round in six minutes and a half; but in doing this at full speed—*i.e.*, when the time of turning is shortest—she describes a circle 1,800 ft. in diameter. The rudder will not turn her without steerage way, and that steerage way involves the awkward consequence, that if the officer in command wishes to turn the ship at full speed through an angle of 90 deg. in order to bring his stem to bear upon an adversary with which he had just exchanged broadsides, he would find himself, at the completion of the operation, a quarter of a mile from the place where he commenced it. I do not take this ship in order to exaggerate the difficulty, but because she has been remarkably successful, and is the perfection of our present system of steering. The "Warrior" and "Black Prince" afford a still more striking illustration, because of their great weight and length.

In the former ship the time occupied in turning completely round at five different trials varied between 7 min. 46 sec. and 9 min. 5 sec., and averaged 8 min. 20 sec. In the "Black Prince," the time at six different trials varied between 8 min. 3 sec. and 13 min. 33 sec., and averege 10 min. and 22 sec. The space traversed by them in turning is so great that in passing through 90 deg., under the circumstances before mentioned, the vessel would have to travel nearly half a mile.

In these ships also the ordinary means of steering are as perfect as they can be made. In the "Black Prince" especially, no pains have been spared to perfect the steering gear; and as some naval officers were of opinion that the rudder was too small, its area has been increased from 151 to 178 square feet. But the "Warrior," which has not been altered, remains superior to her. We cannot suppose that any vessel which was not completely helpless would suffer herself to be run into by such ships.

What are we doing to remedy this undesirable condition of things? One cannot deny that there has been considerable activity of invention with regard to steering; but there seems to be much misapprehension on the part of inventors as to what we really need. An inspection of the models representing improvements in steering which were sent to the International Exhibition last year, was sufficient to show this.

The majority of them related to improvements in the mode of applying manual power to the ordinary rudder; although the advocates of auxiliary rudders, bow rudders, and balanced rudders were not unrepresented; and there were prominent models of double or steering propellers.

Nothing whatever is to be hoped from this first and most numerous class. The only real difficulty to be contended with inside the ship is friction. Neglecting this, no possible alteration in wheel, or tiller, or yoke can reduce the labour of the men, without increasing the time occupied in putting the rudder over. Nor, on the other hand, can this time be diminished without increasing the labour of the men.

We already know how to reduce this friction to a small amount, and should gain very little if we could get rid of it altogether. Inventors in this direction are more likely to excite ridicule than to achieve success.

There are inventions, it is true, for performing the work of turning the rudder by hydraulic or steam power; but supposing such apparatus can be perfected, the condition of things already pointed out in the "Warrior," "Black Prince," "Resistance," and other iron-cased ships as to the time occupied, will in all probability remain. We must therefore look for improvement in the instrument which acts directly upon the water.

And first with regard to the size and shape of the ordinary rudder.

Some gentlemen have very strong opinions on this matter. One eminent shipbuilding firm considers that the lower part of the rudder is of little service, and their rudders are accordingly made *lean* at the bottom. Others are of opinion that no rudder can be good unless it is very *broad* at the bottom; and there are some staunch advocates of a great breadth at the height of the centre of pressure. And then as to size, it has been asserted by eminent naval officers that the rudders of modern men-of-war are too small, and that the sluggishness of the "Warrior" in answering her helm is due to this cause.

Now the first point which has to be considered in regard to these matters is this:—Is the rudder large enough to absorb all the power we can put on it? If we find, as we do find in nearly all our screw-ships, that the men at the wheel cannot hold the rudder at the extreme angle for which it is bearded, but have to exert all their force when the vessel is at full speed in order to hold the helm at 15 or 16 degrees, then we may be sure that the area of the rudder does not require to be increased. There are, in fact, certain considerations which show that, as a general rule, our rudders are *too large*. It will be seen, first, that the further the rudder is put over, the greater is the velocity of the fluid in a direction perpendicular to its surface, or the effective velocity of the fluid. There is therefore an *advantage, so far as increase of pressure is concerned*, in working with a large angle or with a small rudder.

But, on the other hand, the effect of the pressure on the rudder in turning the ship depends on the leverage or on the amount of the pressure about the centre of gravity of the ship, which is in proportion to the length of the perpendicular drawn from the centre of gravity, upon the direction of the resultual pressure. The length of this line diminishes as the angle increases, so that, *so far as this leverage is concerned*, there is a *disadvantage* in large angles and small rudders. A third consideration, pointing to the same conclusion as the second, is, that large angles or small rudders require more time in putting the rudder over, so that the vessel would not answer her helm so readily with a small rudder as with a large one.

And then there is a fourth consideration, to which my attention has been recently directed by Mr. Barnes, of the Department of the Controller of the Navy—viz., that while the outer half of the ordinary rudder does no more in turning the ship than the inner half, it absorbs three times the amount of labour, on account of its distance from the fulcrum. This is another advantage on the side of the small rudder, and one of considerable consequence. He concludes from it that rudders which cannot be worked at large angles, are unecomical, and should be reduced in area until they can be so worked.

If a problem of maxima and minima be constructed, expressive only of the first two conditions laid down here, it appears that the rudder would be most effective in turning the ship if it were over at an angle of 54¾ deg.

But, if the fourth or economical consideration is also brought in as one of the conditions of the problem, so as to discover with what angle and breadth of rudder *a given power* on the wheel may operate most effectively on the ship, the angle comes out 45 deg., and of course the breadth of rudder such that the former will just maintain that angle. Although this undoubtedly shows that rudders which can only be worked at 15 deg. or 16 deg. are too large, I am afraid the necessities of a ship which must be sometimes under sail and sometimes under steam will limit improvement in the ordinary rudder in this respect; for a rudder which could be held hard over when under steam, would certainly be too small when under sail.

Mr. Barnaby then described Mr. Lumley's rudder, and showed that the success obtained with it was very partial, and scarcely affected at all the time occupied in turning. He then proceeded to consider the balanced rudder, in which the rudder surface and the steering power may be increased without acquiring any increase in power applied.

This idea is so promising that it has been often patented. As long ago as 1790 a patent was granted to Charles Earl Stanhope for this invention, called by him an equi-pollent rudder. It has been adopted also in some of Mr. Scott Russell's ships, and I believe in others; but, so far as I can learn, these rudders in screw-vessels have always been placed *before* the screw.

In the recent experiment to which I refer, made by Capt. Key, R.N., this rudder was fitted in a temporary manner *abaft* the screw, and the following facts were established:—

1. With a very small exertion of power, the rudder may be put over to any angle when the vessel is at full speed.

2. That in order to obtain the necessary balance for this purpose, with these relative positions of rudder and screw, the after part of the rudder must be *twice* as large as the fore part.

3. That whereas the ordinary rudder can only be got over to 15 or 16 deg. when the ship is at full speed, and that with great effort, this rudder could be held with ease at angles up to 45 deg., and that by thus increasing the angles, both the diameter of the circle and the time of turning were slightly diminished.

4. It was found that an *increase* in the *area* of the rudder, while it reduced the diameter of the circle described and also the time of describing the first quadrant of the circle, increased the whole time of describing the circle. It was found, further, that, other things remaining the same, an *increase* in the *speed* of the vessel shortened the time of describing the circle, while it *increased* the *diameter of the circle* described.

It has been stated above, that the advantage over the ordinary rudder, with regard to quickness of turning and turning space required, was *slight*. This was probably owing, to some extent, to the fact that the balanced rudder was further from the screw than the ordinary rudder, and therefore did not receive so much assistance from its action upon the water. It is not, however in gunboats, but in ships 300 and 400 ft. long, that the advantages promised by the balanced rudder are wanted. We are told, for example, that the "Black Prince" was, on one occasion, turned completely round in 8 min. 3 sec., the rudder being over to 28 deg.; but, in order to hold it there it required 10 men at the wheel and 30 men at relieving tackles—no less than 40 men being employed at this operation. This is, of course, an extreme case; but it serves to show that an invention which promises to reduce these to one or two men, has great claims to consideration. An advantage which is of slight consequence in small vessels, assumes in these large vessels very great importance.

But, suppose we consider it proved that the balanced rudder would give the advantages we desire, where is it to be placed? We are told that it must not be before the screw, for in that position it has been found to fail. If placed abaft the sternpost, it is subject to the disadvantage of being too far from the propeller, of suffering from the obstruction interposed by the sternpost, of liability to jam by confining loose ropes or other partially sunken matter between the fore edge of the rudder and the back of the post; and, lastly, it requires too great an extension of the stern of the ship. The question to be considered is, I think, this—May we not in our large iron ships get rid of the sternpost altogether, and fit the balanced rudder in its place abaft the propeller?

In the case of the "Northumberland," for example, the after sternpost is a mass of iron weighing 9 or 10 tons. Its only conceiveable uses in this ship are to support the rudder and hold up the stern.

I should not have troubled you to consider the latter of these two uses, if I had not heard it strongly insisted upon by some shipbuilders. I must confess myself at a loss to conceive of what service it can be in this respect. If there were any tendency in the stern of the ship to settle down can it be supposed that the long and comparatively thin forging, extending from the bottom of this post to the body of the ship, would be so rigid as to refuse to bend two or three inches in 10 or 11 ft., when the weight pressing upon its extreme end was some 200 or 300 tons?

To expect the rudder-post to prevent any lateral motion of the stern would be still less reasonable. So far, then, as the strength of the stern of the ship is concerned, may we not remove the rudder-post in such a ship as the "Northumberland"—*i.e.*, in a ship built of iron, and having no after bearings for the screw? But, further, is it necessary for the support of the rudder? And, first, it will be evident, from what has already been said, that although the rudder is supported directly by the sternpost, to which it is hung, yet that indirectly the stem of the ship has to hold both. If instead of attaching the head of the sternpost to the stern of the ship, and hanging the rudder to it, the rudder were taken hold of by the stern and the post were removed, does it not appear that the stern would be actually relieved? If the weight of the rudder were thus taken upon one of the decks, it would be possible to make a considerable reduction in the ordinary friction of turning on the braces. A socket in the end of the keel, for confining the heel of the rudder, would then complete the arrangement. After some considerations as to the use of *auxiliary* and *bow* rudders, of which it was considered very little could be expected, Mr. Barnaby passed to the question of the employment of special machinery for turning the ship, and, first, to the use of double screws. He stated that, from the recent trials of the "Flora" and "Kate," the following facts were established:—

1. That with both screws working ahead, there is no loss of steering power compared with ordinary vessels, the circle being completed in 3 min. 48 sec.

2. That when one screw was stopped, the time of turning under the action of the other screw and the rudder was a little greater—viz., 8 min. 58 sec., but the diameter of the circle in which the vessel turned was about one-third less than before.

3. That with one of the engines reversed, both engines driven at full speed, and the rudder hard over, the time of turning was still greater, viz., 4 min. 16 sec., but the vessel turned upon her own centre.

4. That the vessel could be turned on her own centre by the screws alone, the helm being amidships, but the time occupied in turning was 6 min. 55 sec.

5. That the vessel was under perfect command as well when steering astern, as when steering ahead.

The first thing observable here is, that when the screws are used to assist in steering, the vessel turns more slowly than when under the influence of the rudder alone. This arises to some extent from the fact, that the screw which is stopped or reversed is on the side towards which the rudder is turned, so that the rudder is rendered partially ineffective. It must also be borne in mind that this vessel is narrow in proportion to her length, the screws are therefore very close together, and their leverage in turning the vessel, small. On this account I think we might expect a better result in a broader vessel, where the screws had a greater leverage.

The real gain in this arrangement is, however, the reduction of the space passed over in turning. Our longest ships may by these means be made to turn on their own centres when employing the full power of their engines, instead of making a circuit of nearly two miles.

But we must not conceal from ourselves the fact, that, so far as our experiments have gone at present, we have found no means by which we can quicken the rate of turning in these large ships.

Improvement in this respect has still to be sought. Supposing we were to adopt both the double screw and the balanced rudder, we have no reason to suppose that these large ships could be turned completely round in less than seven or eight minutes. The actual velocity with which the head of the ship moves round in obedience to the helm, *i.e.*, the velocity of the extremities of the ship in a direction at right angles to the length of the ship, Mr. Barnaby finds to be as follows:—

	Length of Ship.	Knots per hour.
Warrior	380 ft.	1.3
Resistance	280 ft.	1.3
Emerald	237 ft.	1.1
Liffey	235 ft.	1.1
Edgar	230 ft.	0.9
Racoon	200 ft.	1.2
Kate, most favourable	165 ft.	1.5
„ when turning with screws and rudder together	165 ft.	1.3
Columbine, with Mr. Lumley's rudder	160 ft.	1.2
Bullfinch, gunboat	106 ft.	1.5

I can imagine no way, said Mr. Barnaby, of increasing this speed, except the introduction of special machinery for turning. I have shown in a diagram a mode by which this might be effected. I find that a screw only 10 ft. in diameter, placed in the bow of the ship, and driven at the speed of 9 knots per hour, would perform the same work in turning the "Resistance," as her rudder would perform when placed at an angle of 24½ deg. and acted upon by the water driven from the screw at 18 miles an hour. If such a screw were connected with a small engine on the deck, or in the fore hold, there would be no difficulty in driving it at twice the speed named above, by which we might hope to obtain both the advantages we seek—viz., *increased speed in turning*, and the means of turning on a pivot from rest.

The disadvantages attending the adoption of such a plan lie upon the surface; but it cannot be doubted that it would give more complete command over the movements of the vessel than that promised by the double screws, while it could be used under sail as well as under steam.

In whatever manner future naval engagements may be conducted, the result of those engagements must largely depend upon the course which is now taken in providing machinery for steering. But in view of contests between ships *cased with armour* and *equipped as rams*, this question takes the very first place; and the issue of an engagement between two ships thus constructed, will depend less upon the power of their artillery and the amount of protection given to the guns, than upon the facility with which the vessels move and turn, and upon the provision made for resisting the blows of the ram. There would be but little time or opportunity for fighting guns. The engine and the steering apparatus must do everything.

And although in the view of operations against fortresses and forces on shore the armour and the ordnance must still retain importance, the vital necessity for the English Navy will always be the means of maintaining supremacy upon the sea, in order to secure our own coasts and commerce.

Nothing can apparently be more desirable for England than such a change in the condition of naval warfare as that indicated; for, in that case, the operations of rapid iron-cased rams would render the transport of large bodies of troops across the channel so hazardous as to make invasion next to impossible.

And this desirable change will also possess the advantage that large crews will become unnecessary, it being the duty of the constructor to furnish the small crew with the means of resisting capture by boarding. But all this lies in the future, and depends upon improvements in the machinery of steering.

The questions proposed by Mr. Barnaby for consideration were as follow:—

1. With regard to the ordinary rudder in screw ships. Can any improvement in the ordinary rudder, either in its form and dimensions or in the mode of applying power to it, be expected to give us such facilities in steering as the exigencies of modern naval warfare demand? And if such improvement may be expected, in what direction is it to be sought?

2. With regard to balance rudders. Looking at the great number of men required to work the rudders of large single screw-ships, at the loss of power by the leverage of the rudder, at the loss of efficiency through the smallness of the angle at which these rudders can be worked, and at the slowness with which such rudders can be put over, would it be desirable to substitute for them a balanced rudder in ships where the sternpost may be removed, and the rudder put immediately abaft the screw?

3. With regard to double screws. Supposing there is a loss of time in completing the circle by the aid of the double screw and a little loss of speed, is the advantage of being able to turn in that circle, without being compelled to move ahead, sufficient to render its adoption in large ships-of-war expedient?

4. With regard to a steering screw. If a steering screw working transversely in the bow of the ship promises to give the same advantages as the double screw with regard to turning on a pivot, and promises also to increase the rapidity of turning—an advantage which it seems impossible to secure in any other way; if, further, a steering screw may be employed when the vessel is not under steam, does it offer sufficient promise to make a trial of it desirable?

In the discussion which followed, and in which Mr. J. Scott Russell (the Chairman), Sir E. Belcher, Captain Symonds, Captain D'Orsay, Mr. Humphreys, Mr. John Dudgeon, Mr. Ditchburn, Mr. Andrew Murray, Mr. Grantham, and others took part, there was considerable difference of opinion on the questions proposed. Mr. Humphreys and Mr. Russell were of opinion that the most desirable arrangement for steering large ships was a large rudder turned by steam power. The former gentleman stated that he was now fitting apparatus for this purpose in six vessels, each over 2,000 tons burden, and said that the time of turning the rudder by this arrangement from hard to port to hard to starboard was 12 seconds.

Mr. Russell and Mr. Ditchburn considered that the sternposts of the large iron ships alluded to were unnecessary; and the second question, proposed by Mr. Barnaby, was answered in the affirmative by several speakers.

The advantages of the double screws were freely admitted; but the loss of speed likely to be caused by their use in large ships was urged as a serious objection to them.

Sir Edward Belcher recommended the ejection of water from apertures in the bow and stern, as an effectual mode of steering heavy ships; this, as was pointed out by Mr. Barnaby, amounted to the same thing as the steering screw referred to in his last question, which is in fact a simple and effective jet propeller.

Mr. Scott Russell expressed his fears that the steering screw would interfere with the speed of the ship, and considered that it was on that account undesirable.

THE MID-LEVEL COMPENSATION CASE.

A Norwich special jury, under the presidency of Lord Chief Justice Earle, have been engaged for five days in investigating an action—Coe *v.* Wise, Clerk to the Mid-Level Commissioners, for negligence in not making and maintaining the outlet sluice of the Mid-Level, by reason of which the tidal waters broke through and ran over the sluice, submerging the plaintiff's land. The importance of this trial may be estimated from the fact that no fewer than 107 compensation claims have been awaiting its decision. From the evidence it appeared that, in order to get rid of the drainage that for a long time used to fall into the river Ouse, as effectively as possible, the Commissioners cut a straight line, eleven miles in length, through the country known as Marshland, from Popham's Eau to the Marshland sluice running into the Ouse. An Act of Parliament was obtained for this purpose, which Act directed that a substantial sluice should be made at the end of the cut next the river. The corporation thereupon built a sluice as directed, which was done between the years 1844 and 1846, and consisted of a sort of bridge of three arches, each arch being stopped with doubble sluice doors, opening and shutting with the advancing and receding waters. The banks sloped on each side of this bridge gradually down to the bed of the river, which at the highest tide rose to about 18 ft. On Saturday, the 29th of March, last year, two holes were observed down against the south sea wing. The tide was ebbing, and the water was very muddy, boiling up under the north abutment of the south arch—showing that the water was going from the river into the cut under the bank. Two days later the holes were filled up to the level; and by the 27th of the succeeding month, the same holes had dropped again much larger. Two or three carts were then employed in filling them up, but they fell in again twice. According to the evidence of Samuel Smith, sluice-keeper at the Marshland sluices, who was present at the time of the accident, the whole wing wall went down in less than 20 minutes after he had warned the men that the waters had "burst up." "The earth," added the witness, "must have gone between the piles, and the piles were hanging by the bolts that fastened them to the top." On the Sunday, this witness saw the planks which formed the floor of the sluice in the cut move up. This was on the 4th of May, when the sluice was totally destroyed; and before nine days had elapsed 6,000 acres of land were submerged, and their crops entirely destroyed. It appears that between the 27th of March and the day on which the accident occurred, a great many men were employed in taking steps to prevent the occurrence.

For the plaintiff, Sir John M'Neil, Sir John Rennie, and a few other witnesses were examined. The pith of their evidence was that sufficient precautions were used to prevent the accident. Mr. Fowler, Mr. R. Lunn, the superintendents of the works; Mr. Hawkshaw, the engineer, and other members of the Institution of Civil Engineers, were examined, and on Monday morning the Lord Chief Justice put it to the jury,—First, was damage caused to the plaintiff by the absence of due care and skill on the part of the defendant in making the sluice; secondly, in maintaining the sluice; thirdly, in providing remedies against mischief after the sluice was destroyed; and fourthly, by reason that no puddle clay wall was made along each side of the banks of the cut?—The verdict was declared for the defendant on the first issue, and for the plaintiff on the last three issues: virtually a verdict for the plaintiff. The question of damages is to be settled out of the Court.

The annual dinner of the members of the Institution of Civil Engineers, which was fixed for Wednesday, the 22nd inst., has been postponed, owing to a domestic calamity in the family of the President.

DYSON'S MACHINERY FOR FINISHING AND POLISHING CIRCULAR METAL RODS.

FIG. 1.

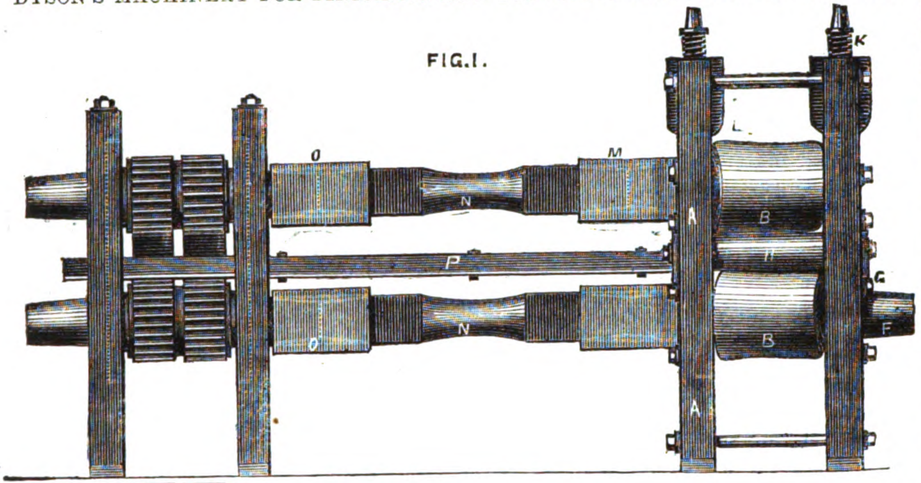


FIG. 2.

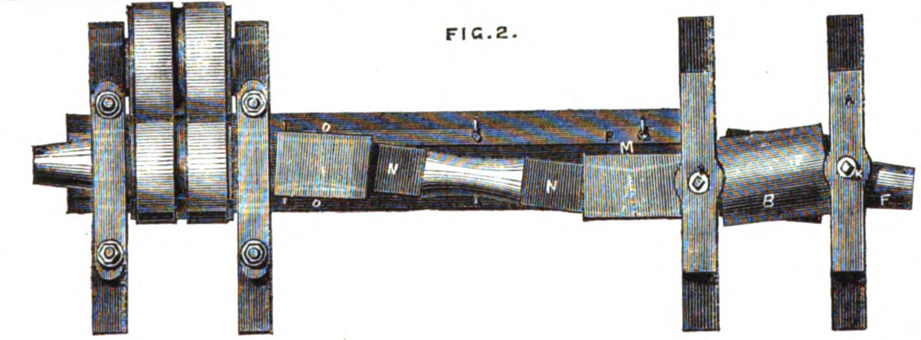

FIG. 3.

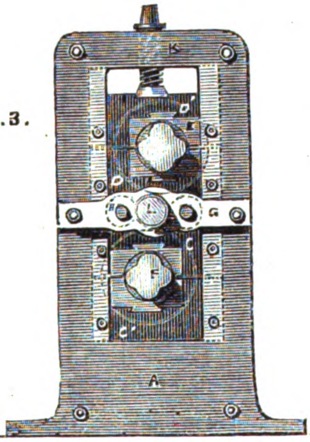

FIG. 4.

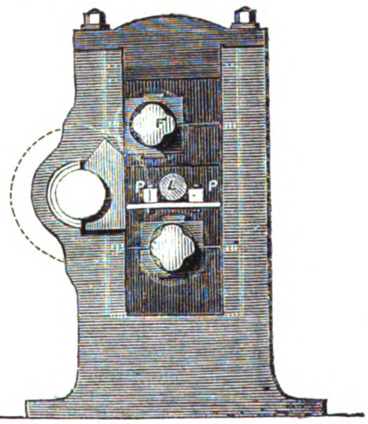


DYSON'S MACHINERY FOR FINISHING AND POLISHING CIRCULAR METAL RODS.

A PATENT has just been granted to Mr. G. Dyson, of Tinsley, Yorkshire, for an invention for "Improvements in machinery for finishing and polishing circular metal rods, bars, and shafts; applicable also to the manufacture of tubes and pipes."

The machinery consists of a pair of rolls, set slightly at an incline, and each inclined in an opposite direction to the other, both rolls being driven in the same direction. The rod, bar, or shaft is introduced between guides and between the ends of the rolls, and at right angles or nearly so to the direction in which the rolls are driven; then, upon the rolls being made to rotate through toothed gear, the rod, bar, or shaft is drawn between the rolls in a direction at right angles or nearly so to the circumference thereof, and is thereby rendered cylindrical, smooth, and polished.

The finishing and polishing machinery is shown in the accompanying engravings.

Fig. 1 is a front elevation; fig. 2, a plan; fig. 3 is an elevation of the "housings" for the rolls; and fig. 4 is an elevation of the housings for the pinions or toothed driving gear. These pinions are arranged to drive both rolls in the same direction, and being such as are generally used in driving rolls, need no further description.

A, A, are the housings for the rolls; B, B, are the rolls, the barrels of which are inclined horizontally, and each in an opposite direction to the other; C, C_1, and D, D_1, are the chocks supporting the brasses E, E, in which the necks of the rolls revolve; F, F, are the tenors of the rolls; G is a strap fixed to the housing. A similar strap, not shown, is fixed to the corresponding part of the housing. These straps receive the spindles of guide rollers H, H, which keep the rod or other article, while being acted on by the rolls, in its proper position between them. Guides in the form of flat bars or square blocks may be used in lieu of the rollers. To keep up the upper roll, spiral springs are inserted between the chocks C and D; K is a pressure screw for regulating the pressure between the rolls; L shows the position of a rod passing between the rolls. It will be observed that the axes of the rolls and of this rod are not in the same vertical plane; M, M, are coupling-boxes shaped on the inside to correspond with and receive the tenors on the inner sides of the rolls, and also the coupling spindles N, N, which are similarly shaped in section to the tenors; O, O, are other coupling-boxes connecting the spindles N, N, to the tenors of the driving gear; P is a support on which the rod or other article is received after passing between the rolls and guided out through the pinion housings. The rod, bar, or shaft should be first prepared by being made more or less round in the ordinary manner by means of grooved rolls, and while still hot is introduced between the outer ends of the the inclined rolls before described. The rotation of these rolls causes the rod, bar, or shaft to pass through the rolls and to issue from the opposite end circular, smooth, and polished.

When applied to the manufacture of pipes and tubes the machinery remains as before described, but in addition to the guides, a mandril is employed between the rolls over which the pipe or tube is drawn.

JENKINS' AND JUMELLE'S IMPROVED ENGINE GOVERNOR.

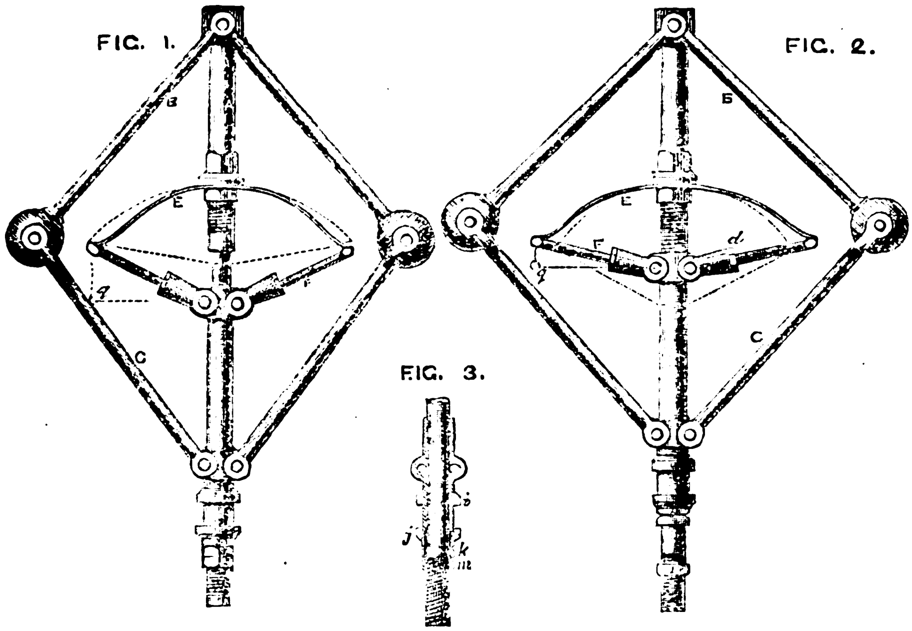
A PATENT has just been issued to Messrs. Jenkins and Jumelle, of Philadelphia, U.S.A., for an improved governor for steam engines, which consists in combining a spring with a governor spindle and rods so arranged as to form a knee, joint, so that the force applied to overcome the rigidity of the spring may be transmitted through a leverage constantly increasing as the resistance of the spring increases, thereby equalizing the action of the spring, a desirable object to be attained, under certain circumstances.

A represents the spindle of the governor, and B and B the weighted arms hung to the top of the spindle in the usual manner. To the weights *a*, *a* of the arms B and B are jointed the upper ends of the rods C and C, the lower ends of the latter being connected to the sleeve D, which is fitted snugly to, but arranged to slide freely on the spindle A; E is a spring connected at a point midway between its opposite ends to the spindle A by means of nuts, which are adapted to the screwed portion of the said spindle.

To each end of the spring is jointed a rod F, each rod being connected to a coupling G by means of a nut, each of the couplings are connected to a lug on the upper end of the sleeve D. The lower end of the sleeve has a recess for receiving the end of the usual governor lever, through which the movement of the sleeve is communicated to the throttle valve of the steam engine; this recess being formed by collars on the sleeve. The lower collar limits the downward movement of the sleeve, and consequently the inward movement of the weights.

On reference to fig. 1, the sleeve D is illustrated as depressed to the limit of its downward movement as regulated by the nut. As the governor revolves the weighted arms will fly out, and the sleeve will rise to an extent regulated by the speed of the governor and the rigidity of the spring E. Now, supposing this spring acted directly on the sleeve without the intervention of the rods F, it will be evident that the higher the sleeve rises, through the centrifugal force of the weights, the greater will be the opposing force presented by the increased rigidity of the spring as the opposite ends of the latter are raised, consequently the govenor will be irregular in its movement, the irregularity being in proportion to the difference in the rigidity of the spring as the ends of the latter are raised. By connecting the spring to the sleeve by means of the rods F, however, the case is different, as they form with the sleeve and spring the well-know knee-joint, so that as the sleeve is raised it acts on the spring through a constant leverage, gradually increasing as the sleeve rises, and as the rigidity of the spring increases. Thus, in fig. 1, where the sleeve is depressed to the limit of its downward movement, the force applied by the revolving balls tending to raise the ends of the spring, will be applied through a leverage equivalent to that represented by the dotted lines, the former representing the long arm of the lever

JENKINS' AND JUMELLE'S IMPROVED ENGINE GOVERNOR.



acted upon by the sleeve, and the latter the short arm acting on the spring, and the point *q* being the fulcrum of the lever. As the sleeve rises the long arm of the lever becomes gradually longer and the short arm shorter, so that by the time the sleeve has arrived at the position shown in fig. 2, the leverage on the spring will have been increased to the proportion represented by the dotted lines in that figure.

ON IRON-CASED SHIPS OF WAR;

Including a Description of H.M.S. "Enterprise," and some Remarks on Sea-going Shield Ships.

Mr. E. J. Reed read a very able Paper on this question at the Fourth Session of the Institute of Naval Architects on the 27th March last. We are sorry that our limits will not permit us to insert the Paper entire. After some introductory observations Mr. Reed said:—

"I will speak first of a few general features of construction which seemed to me worthy of adoption. These are: that we should employ iron armour of some kind, and to some extent, in every class of fighting ship that will carry it, large and small; that we should employ a few large guns wherever practicable in preference to many small ones, and give these large guns as great a range of fire as possible; that every class of ship should be protected with armour throughout her entire length in the region of the water-line; that the rudder-head and steering apparatus should be protected; that every vessel intended for sea-going purposes should stand up well out of the water, be well lighted and ventilated, and carry efficient masts and sails—in fact, be as unlike the ill-fated 'Monitor' in all these respects as possible; that every such vessel should be made strong enough to stand the shock of being used, upon an emergency, as a ram against vessels of her own class; that small war-vessels, if armour-plated, may be built of wood, but that, when a very high speed or very large dimensions are required, we should build in iron; that when built of wood, the hull should be made solid throughout in the wake of the armour; and, finally, that every sea-going ship-of-war should be so formed and have her weights so distributed that she will be well supported, as far as may be, at every part, and have no heavy overhanging parts to cause her to strain and work when knocked about in a sea-way."

After an emphatic condemnation of the new American vessels, like the "Monitor," Mr. Reed said:—"If any thought, or word, or act of mine can have weight, now or hereafter, directly or indirectly, in shaping in any measure the future of the British navy, it shall be employed in resisting every approach to a surrender of that power and predominance upon the open ocean in which we have gloried for ages past, and hope to glory for ages to come. I wish to insist upon this somewhat urgently, because we are tempted in many ways, and by many persons, to compromise the sea-worthy character and sailing qualities of our men-of-war. Ships without a mast or sail; ships with open upper decks not half-a-dozen feet above the water; ships without a cabin in which men can inhale a breath of fresh air, and without a mess-room in which they can eat a meal decently; ships which are much more likely to carry our flag down to the bottom of the ocean than to bear it proudly over it to distant climes—ships of this sort, I say, are continually thrust forward as great improvements by ignorant or designing persons, and not unfrequently find enthusiastic advocates. I trust, however, that we here assembled are agreed at least in this—that the war fleet of England should consist mainly of vessels in which our noble seamen, of all ranks, can live healthily and happily, and seek the open sea at all times with security and confidence."

Much has been said of Mr. Reed's preference for wood. He deals with his critics in the following manner:—

"When we want a ship to perform the service allotted to our sloops and corvettes in all quarters and corners of the globe—when we want a vessel to go steaming in and out harbours, and up and down rivers, and to go feeling her way over unexplored grounds—then I have not a moment's hesitation in deciding that she may with great satisfaction have her hull built of wood. I am not going to say I condemn iron altogether as a material even for ships of this kind, but neither am I going to condemn wood for the purpose, and I say it would be mere idle theorizing to deny that wooden bottoms are exceedingly valuable in small war-ships designed for foreign service. But then, on the other hand, if we wish to build a ship that shall be driven, say, at 14 knots of speed, there is not one among us, probably, who will doubt that iron is by far the best material for our purpose. It is only just to myself to state most distinctly my preference for iron und r such circumstances, because, from the fact that the first vessels built by the Admiralty from designs prepared by me happened to be of wood, some persons have fallen into the error of supposing that I am averse to iron ships. No greater mistake could be made. The very first design submitted to the Admiralty by me, was for a high-speed iron-cased ship of iron, and I have had in hand for some time past other designs which are to be of iron, and in the carrying out of which I have had the honour to receive great encouragement from the Controller of the Navy. For the truth is, there is no actual difference of opinion at all, that I can find, on this important question. Everybody is thoroughly convinced that, for such colossal and fast vessels as the 'Warrior' class and the 'Northumberland' class, iron is not only the best material, but the only material that we can wish to use, and I never yet met with any one who questioned that fact. No one ever proposed, I believe, to build such ships as those of wood. But then it would be utterly vain and futile to deny in this place, and before this assemblage, that great manufacturing difficulties and imperfections exist in connection with iron ships."

After some pertinent extracts from Mr. Scott Russell and Mr. Grantham, on some of the difficulties attending the use of iron in ship-building, the author of the Paper gave the following description of the "Enterprise":—

"The frame timbers of this vessel were to a large extent converted, so that I laboured, of course, under some considerable difficulties—a fact which, if I may say so, my critics have sometimes kept out of sight. The principal features of the 'Enterprise' were designed in this way: In the first place, I fixed upon four 110-pounder shell guns as a sufficient armament to replace the numerous small guns which the ship would have carried if completed as an unprotected wooden ship. These four large guns I determined to place in the centre of the ship, in order to give them, and the armoury which was to shield them, the support of the buoyancy which abounds at that part of the vessel. Upon the sides of the ship I placed 4½-inch armour to to protect the guns, extending it from a sufficient height above, down to the neighbourhood of the water-line. Below this armour I found I could place a tapering belt of armour plates, reaching from a foot or so above the water-line to 3 or 4 ft. below it, making it 4½ in. thick at the upper and somewhat less at the lower edge. This belt I extended over the whole length of the ship, from stem to stern, raising it an extra foot or two at the stern to shelter the rudder-head and tiller. To prevent the battery from being raked, I fitted transverse bulkheads at its extremities, just as such bulkheads are fitted in the 'Warrior,' and for precisely the same object, and over the guns I fitted a solid roof or deck, surfaced with iron, to protect them and the gunners. I next raised the decks a foot or two in order to bring the lower deck above the water, and coincident with the upper edge of the armour belt, and to this deck also I gave a surfacing of iron, in order to assist in causing any shot that might strike it to glance. The exposed unprotected portions of the ship I at first proposed to fill in solid, so as to render them less combustible; but I suggested that these light exposed upper works might be formed of iron, and thus made entirely incombustible, and this suggestion was approved by the Admiralty Constructors and adopted by the Board. There are, however, two other points which I must not fail to mention—namely, the adoption of an arrangement of transverse ports and short turn-down bulwarks, by which I am enabled, for the first time in naval construction, I believe, to get an almost fore and aft fire from a protected battery with a broadside gun; and, secondly, the method of solidifying the frame by means of dowelled fillings behind the armour. I also gave to the other timbers an increase of scantling.

* * * * * *

"As regards the other vessels which I am superintending—the 'Research' and 'Favourite'—they differ from the 'Enterprise' in some very important respects. I was fortunately disembarrassed, as regards those vessels, of several limitations that fettered me in the "Enterprise," and being anxious to produce a class of ship of which several might be commenced with confidence, I avoided in them the iron upper works, and have provided for plating them up to the upper deck; so that these two ships, of about 1,250 and 2,180 tons respectively, will be as completely plated with 4½-inch armour as the largest iron-cased ship in existence. Extra strength has been thrown into the bows of all these ships, so that they may be strong if used as rams; and you will see that, owing to the concentration of all the principal weights at the centre of the ship, that association of weight with buoyancy which Mr. Scott Russell and Mr. Grantham have so urgently recommended, and those improved steering qualities before mentioned have been attained in a very unusual degree."

Mr. Reed then vindicated the "Enterprise" from the attacks made on it by Admiral Halsted. "You have heard," said he, "my description of the vessel, and by what process she was designed, and you will be able to see for yourselves how entirely free she is from both the merits and the demerits peculiar to the cupola plan. In point of fact, cupola ships are the only kind of war ships to which the 'Enterprise' bears no sort of real resemblance; for between her and the ordinary broadside vessels there are comparatively few vital differences. I know, however, how the gallant Admiral got led into his error. It has so happened that, owing to the large quantities of bad iron which have been sent in repeatedly for the ship by contractors, and, of course, as repeatedly rejected, we have been unable to proceed as rapidly with the ends of the vessel as with the midship portion, which is of timber, and therefore free from difficulty; and the consequence has been that the battery of the ship has been left standing up like a tower, and so as to look to a hasty observer something like a square cupola, if I may imitate Admiral Halsted in the use of such a phrase. Ere long the ends of the ship will be built up and her appearance so much altered, that every one will wonder what Admiral Halsted could possibly have meant.

* * * * *

"Admiral Halstead says the 'Research' is three-fourths unprotected; the answer is, that the 'Research' is as completely protected on the broadside with 4½ inch armour as any ship in the service, for the armour rises quite up to the upper deck and to the top of the battery. Admiral Halsted says the 'Research' is being built after an attempt to combine iron topsides upon wooden bottoms; the 'Research' has, however, no iron topsides at all, and was never designed to have any. The 'Enterprise' is being built upon that principle; but the Board of Admiralty thought it prudent to get her to sea before they laid down other vessels on the same plan, and to await the experimental solutions of the problem. No second vessel of the kind, therefore, was commenced; and, with the strongest desire to be indulgent, I confess myself utterly incapable of conceiving why a gentleman should have rushed into print with a directly contrary statement.

"One other point requires attention. It has been a favourite practice with the one or two writers before referred to, to speak disparagingly of the strength of the 'Enterprise's' side; and my gallant friend has followed in their track. He and they seem to consider it a great discovery to have found out that the 'Enterprise's' side, although covered with 4½-inch plates, will not be quite so strong as the side of the 'Warrior,' or as the 'Trusty' shield; and they solemnly suggest that the Admiralty should spend a thousand pounds or so an an experiment to ascertain if their view is not correct. I can assure them that the Admiralty will not incur the expense, for they know perfectly well already that the 'Enterprise's' side is not fully equal in strength to those structures. Of course we have all along known, and everybody with a grain of common sense must know, that a wooden sloop's side, even when strengthened like the 'Enterprise's,' being without an inner iron skin, must be somewhat weaker than the 'Warrior's,' which has a stout inner skin. But I should like to ask Admiral Halsted and his allies, whether any sloop's side was ever made as strong and impregnable as a line-of-battle ship's? And I would ask them further, whether they do not consider it would be more fair and reasonable to compare the 'Enterprise' with the class of vessel which she is intended to replace—the old wooden sloop, with frames 5 or 6 inches thick only, and with great spaces between them, and with no armour at all—rather than to compare her with the largest iron-cased ship yet afloat—a ship ten times her size?"

From Admiral Halsted he proceeded to answer Captain Coles:—

"I may remark," said Mr. Reed, "that we must drop the notion with which Captain Coles seems to have started, and which was embodied in the 'Trusty' shield. We have no longer to do with cupolas, for he has now adopted turrets, or upright cylinders like the 'Monitor's,' which are very different things from sloping shields. They are different, first, because they no longer protect the gunners from vertical fire. The gunners may, of course, be protected from such fire by covering the turrets over; but this requires special armour for the purpose. The same armour no longer effects both objects. They are different also because they no longer have the advantage so much insisted upon by Admiral Halstead, of glancing the shot off them. Capt. Coles's turrets are now made 25 ft. in diameter, and therefore always present square to the enemy a surface, say 10 ft. wide and 6 or 7 ft. high, in which there is only a single foot of curvature. At short range, and with modern accuracy of fire, this surface would be struck by every shot, and always be struck square; for in whatever direction the enemy may lie, the turret will be much worse off than an ordinary ship's side battery, which can never be struck square except when the enemy lies quite opposite to it.

"We must also drop, for the present at any rate, the notion that we can fire more rapidly from a turret than from the broadside. This was done in the 'Trusty' because the gun was breech-loaded, and ran out of itself. But we are now to carry 300-pounders in turrets, and we have no breech-loading guns of that size, nor are we likely to have; and consequently it would be a pure assumption to suppose that we can fire faster in turrets than out of them. In fact, until we have had actual practice with 300-pounders in 25-ft. turrets, we cannot be sure that they can be loaded and fired with anything like the same convenience and rapidity as broadside guns, especially if we take to training broadside guns mechanically.

"Further, the change from cupolas to turrets has left us in doubt whether such apparatus will stand the fire of heavy ordnance. The blow of a 300-pounder upon an upright cylinder may have a very different effect to the blow of a 68-pounder, or a 100-pounder, upon a sloping shield. It may hereafter be proved that such a structure will stand such a fire, but at present the matter is in doubt."

He then proceeded to speak more particularly of sea-going shield ships in the following words:—

"Now, if a ship is to be fit to go to sea at any time and at all times, you must not give her a deck close down to the water, and nothing above it. In a shield ship you can have no permanent bulwarks above your upper deck, or else you cannot fire all round, which it is the special merit of the shield to do. Your upper deck itself, therefore, must be well up out of the water, and the longer you make the ship, and the higher speed you give her, the higher this deck must be. I should think the deck of no sea-going ship whose bulwarks must turn down in action ought to be less than 5 or 6 ft. out of the water; otherwise the sea would wash over, and destroy the health and comfort of the crew. If, then, we assume that the ship is to be plated up to this deck all round, and that the armour is to reach down as usual to, say, 4 ft. below the water, we at once get a depth of 9 or 10 ft. of armour all around the ship, in addition to the armour of the turrets. Here, then, at the very outset, all hope of a small sea-going turret ship wholly armour-plated, to steam at a fair speed, is at once annihilated. If we take a vessel no larger than the 'Enterprise,' for example, we at once find that we require about 400 tons of armour and backing (taking 4½ in. iron on 18 in. of teak) on the side only; and if we put into her but a single turret to carry a couple of 300-pounders, we must add, say 120 tons for its weight; so that our armour alone will weigh considerably over 500 tons. Now, I am sorry to say—and no naval architect will contradict me—that we cannot possibly carry this amount of armour on a vessel of the size of the 'Enterprise,' and still preserve the buoyant, and steaming, and sailing, and steering qualities which she possesses. Our smallest shield ship, carrying but a single turret, if wholly plated, and made sea-worthy, must be considerably larger than that vessel. I have not seen a one-turret sea-going iron-plated ship; but I have seen a two-turret vessel of that kind building in the dockyard of one of our very foremost private shipbuilders; and I will tell you what she is like. She is, if I remember rightly, about 240 ft. long; is of considerably more than *twice* the tonnage of the 'Enterprise,' has an upper deck only about 4 or 5 ft. from the water, and armour only 3 ft. below it; has only 9-inch teak behind 4½-inch armour; has but comparatively little steam power; has no prospect of sailing well; and yet has had that all-round fire which is supposedto be the chief merit of cupola ships sacrificed to a very large extent by the erection of permanent bulwarks forward and aft. In fact, the power of firing either ahead or astern is not possessed by her, for without these permanent bulwarks she would be unsafe at sea; and it remains to be seen whether she will be safe even under this disadvantage."

Our space will not permit us to give the remainder of this very able Paper.

ON THE ACTION OF SULPHURIC ACID UPON LEAD.

By T. Crace Calvert, F.R.S., F.C.S., &c., and Richard Johnson.

It has been generally supposed by scientific men, but we do not know upon what grounds, that metals are less acted upon by acids in proportion to their greater degree of purity; and it naturally follows that smelters strive to attain to a continually increasing purity in the metals they produce. This is especially the case in the manufacture of lead, because the process which purifies the lead enables the smelter to extract from it other substances, such as silver, rendering the operation profitable in itself.

It is, however, very desirable to ascertain whether the opinion generally held respecting the diminished action of acids on metals in proportion to their purity, is really correct or not as regards lead; and hitherto we are not aware that any experiments have been made with the view of determining this question. We have, therefore, thought that it might be interesting in a scientific point of view, as well as practically useful, to study the action of acids, and especially that of sulphuric acid, upon some of the leads of commerce, which, as is well known, are largely employed in the construction of those immense chambers in which sulphuric acid is manufactured.

With this object in view, we have instituted a series of experiments to ascertain the action upon lead of sulphuric acid of various degrees of concentration and purity, in different volumes, at various temperatures, and for various periods of time. We have made use of two kinds of commercial lead, choosing as types the two extremes in respect of purity, viz., common sheet lead, representing ordinary impure lead, and virgin or Derbyshire pig lead.* We have also

---

* The analysis of the two classes of lead upon which most of our experiments were made yielded the following results:—

	Common lead.	Virgin lead.
Lead	98·8175	99·2060
Tin	0·3955	0·0120
Iron	0·3604	0·3246
Copper	0·4026	0·4374
Zinc	traces	traces
	99·9760	99·9800

thought it desirable to examine the action of sulphuric acid upon chemically pure lead; and we may at once state, as the result of three or four repetitions of such series of experiments, all agreeing closely with each other, that we have arrived at a conclusion directly opposed to the generally received opinion; for we have found that the purer the lead in contact with sulphuric acid, the more it is acted upon. Thus the action on pure lead is from two to three times as great as that upon the common kinds, as will be seen by the following results:—

Thirty square centimetres of each of the different kinds of lead, were acted upon (at ordinary temperatures of 64° to 68°) by 50 cubic centimetres of perfectly pure sulphuric acid, and at the end of ten days the following quantities of lead were dissolved:—

	II.—0·006	0·011	0·023
	Mean... 0·0065	0·0130	0·0205

The next Table gives the above results calculated for a metre of surface (instead of 30 centimetres) acted upon by a proportionate quantity of acid (16·666 litres).

Table No. 2.

Density of acid employed.	Common Lead.	Virgin Lead.	Pure Lead.
	gr.	gr.	gr.
1·842	67·70	134·20	201·70
1·705	8·35	16·50	19·70
1·600	5·55	10·34	16·20
1·526	2·17	4·34	6·84

These results leave no doubt that the purer the lead the more it is attacked, and that in a ratio which is very curious and instructive.

In another series of experiments, made with the same leads, and under the same conditions, with this difference, that the period was fifteen instead of ten days, the following are the results calculated for a square metre:—

Table No. 3.

Density of acid employed.	Common lead.	Virgin lead.	Pure lead.
	gr.	gr.	gr.
1·842	89·00	194·34	279·00
1·705	11·67	16·84	24·00
1·600	6·17	12·17	20·00
1·525	3·17	8·67	8·67

These results confirm the above.

If, instead of a natural temperature, we operate at a temperature of about 120 deg. for eight days, we still find, as in the preceding instances, that the action of the acid on the purer lead is more energetic than on the ordinary qualities:—

Table No. 4.

Density of acid employed.	Common lead.	Virgin lead.	Pure lead.
	gr.	gr.	gr.
1·842	418·34	458·50	507·34
1·705	6·84	10·67	13·00
1·600	5·84	6·34	11·84
1·526	3·50	4·84	6·67

The question occurred to us, whether the purity of the acid employed had occasioned such unexpected results, and whether the substition of ordinary commercial acid would not show a different relative intensity of action. We, therefore, used some acid from the leaden chamber, and which had undergone no purification, its density being 1·593. The following results were obtained from two series of experiments, continued for fifteen days, at the temperature of from 113 deg. to 122 deg.:—

Table No. 5.

Density of acid employed (from leaden chamber).	Common lead.	Virgin lead.	Pure lead.
	gr.	gr.	gr.
1·593	I.—11·84	15·84	19·50
	II.—11·34	16·17	19·84

If we employ twice the quantity of acid to the same surface of lead, other conditions remaining as in the preceding experiment, we find that the action increases in each case with the purity of the lead, but not in the proportion of one to two. The following table gives the mean results of two distinct series of experiments:—

Table No. 6.

Density of acid employed (from leaden chamber).	Quantity of lead dissolved in 15 days by the action of 33·333 litres of acid upon one square metre of surface.		
	Common lead.	Virgin lead.	Pure lead.
	gr.	gr.	gr.
1·593	I.—20·17	22·50	27 00
	II.—22·17	24·34	27·67

We repeated these experiments, employing acid not as it comes from leaden chambers, but after having been once evaporated in open leaden vessels in which its concentration is commenced commercially. The following table gives the mean figures obtained from two distinct series of experiments, with one volume, and with two volumes of this acid, in each experiment the acid used was obtained from a different source:—

Table No. 7.

Density of acid proceeding from open leaden vessels, in which its concentration is commenced in commerce.	Quantity of lead dissolved by the action of 16·666 litres of acid for 15 days at temperature of 113 deg. to 122 deg. upon one square metre of metallic surface.		
	Common Lead.	Virgin Lead.	Pure Lead.
	gr.	gr.	gr.
1·746	I.—49·67	50·84	55·00
	II.—51·91	54·75	57·41
	Quantity of lead dissolved by 33·333 litres instead of 16 666 litres of acid, the other conditions remaining as above.		
	gr.	gr.	gr.
1·746	I.—54·67	56·17	59·34
	II.—56·25	58·67	60·67

We have confined ourselves to a few particulars without entering at length into all the details of our experiments. We may, however, state that they were all repeated many times, and that we varied the surfaces of lead, the quantities of acid, the temperature, the duration of action, and, in fact, all the conditions of the experiments; and yet we always obtained similar results, from which we draw the following conclusions:—

First, and this is the principal point to which we invite the attention of scientific as well as practical men. Of the various kinds of lead existing in commerce, the purer they are the more they are acted upon by the sulphuric acid. Lead chemically pure is more acted upon than any of the others.

2. Although it is stated in many chemical works that sulphuric acid only acts sensibly upon lead at a temperature above 383 deg., our experiments tend to prove the contrary, since we find that acid of sp. gr. 1·842 dissolves *cold* 67, 134, and even 201 grammes of lead per square metre of surface; and, in another instance, that acid of sp. gr. 1·705 takes from the same surface 54, 56, and 59 grammes of lead at a temperature of about 120 deg. only.

3. Finally, the action of sulphuric acid upon lead appears, at least, when there is no continuous agitation of the mass, not to increase in proportion to the quantity of acid employed. This is probably due to the formation of a layer of sulphate of lead, which protects to a great extent the surface from further action by the acid.

The various experiments which form the subject of this Paper lead to conclusions so unexpected that we think it advisable to state the circumstance which first induced us to undertake the investigation.

In the course of the year 1860, a very extensive chemical manufacturer consulted one of us respecting his leaden chambers, one of which had been in use for fifteen years, and remained apparently in good condition, whilst another, less than one year old, was attacked on all sides, its interior being furrowed with fissures.

Having taken a piece of lead from the sound chamber (No. 1), and two samples from the injured one, the first (No. 2) from a part still uninjured, and the second (No. 3) from a place attacked by the acid, we submitted these samples to analysis, and were surprized at the following results:—

	1.	2.	3.
Lead	98·87	99·37	99·45
Tin	0·91	traces	traces
Iron	0·12	0·37	0·32
Copper Zinc	Traces	0·16	0·17

These figures show that the chamber which had so long resisted the action of the acid was made of lead differently and more largely alloyed than that of which the other chamber was made. The question then arose which we have endeavoured to answer in this Paper.

There is yet another question to be solved, viz.:—What metal is it which, mixed with lead, enables it to resist the action of the sulphuric acid, and in what proportions should that metal exist in the mixture—is it, as the foregoing analysis would appear to indicate, tin? We hope at a future date to be in position to answer this question.

Meetings for the Week.

Mon.—*Medical Soc.*—Clinical Discussion, at 8 p.m.

Tues.—*Inst. Civil Engineers.*—I. Discussion upon Mr. Miller's Paper "On Structures in the Sea." II. "Description of the Line and Works of the Scinde Railway," by J. Brunton, Esq., at 8 p.m.
Royal Inst.—"On Animal Mechanics," by Prof. Marshall, at 3 p.m.

Wed.—*Soc. of Arts.*—"On the new Art of Auto-Typography," by Geo. Wallis, Esq., at 8 p.m.

Thurs.—*Royal Inst.*—"On the Relations of Geology with Allied Sciences," by D. T. Ansted, Esq., at 3 p.m.
Inventors' Inst.—"On the Effect of the Periodical Payments at the End of the Third and Seventh Years, respectively, on the Patent System, and Interests of Inventors," by Thomas Webster, Esq., M.A., F.R.S., at 8 p.m.
Antiquaries.—At 8.30 p.m.

A New Safety Mining Lamp.—Welsh magistrates resident in the great coal basin of South Wales have lately had their attention called to the sad thoughtlessness of miners. At a colliery near Aberdare an explosion occurred a short time ago, by which nine men were injured and two killed; and it was elicited at the inquest that one of the deceased in all probability caused the explosion by opening his lamp for the purpose of "having a smoke." Numerous single instances of men tampering with their lamps for the same purpose have also been brought to light. The latest lamp invented possesses a marked superiority over its predecessors. A collier in North Wales, by name Isaac M. Evans, is the inventor. The Davy has this objection, that the gauze covering or envelope renders the light obscure, and practical colliers say that they cannot fill so many trams in a week by its light as by the light of a common candle. Hence it has been known for colliers working in a dangerous stall to open their lamps or put them aside and use a candle instead. Evans's lamp obviates this difficulty or defect. Around the light is a thin glass tube, purposely made thin so as to admit of expansion. Over this again is a stouter glass envelope, strong enough to bear being knocked about with impunity. At the top are two gauze cones, and at the base the air is admitted to the lamp by means of punctures. The point of the invention, it would appear, was to construct a lamp that should give equal light to that of a candle, that should warn the collier of the presence of gas, and, on the assumption that he with usual rashness would disregard the warning, should go out and leave him in the dark. These conditions are said to have been fulfilled. With a lamp as this is hoped to be, and a more rigid system of detection, selecting men from amongst the colliers themselves as inspectors over their own and their fellow-workmen's safety, the foul gas of our coal mines may become of less import, and coal fires less suggestive of disaster and death.

TO CORRESPONDENTS.

The Mechanics' Magazine is sent post-free to subscribers of £1 1s. 8d. yearly, or 10s. 10d. half-yearly, payable in advance. Post orders made payable to Mr. R. A. Brooman, of 166, Fleet-street, E.C.

Advertisements are inserted in the Mechanics' Magazine at the rate of 6d. per line, or 5½d per line for 6 insertions, 5d. per line for 13 insertions, 4½d. for 26 insertions, and 4d. a line for 52 insertions. Each line consists of about 10 words. Woodcuts are charged at the same rate as type. Special arrangements made for large advertisments.

To insure insertion in the following number, advertisements should reach the office not later than 5 o'clock on Thursday evening.

Correspondents who wish their manuscripts to be returned are requested to state this.

We beg our correspondents to choose initials, rather than general signatures such as "Constant Subscriber," or "Reader," &c.

Received.—J. C., V. P., C. W. L., J. N., H. K., Capt. B. B., M. M., Prof. C. C.

W. M. N. (Manchester).—Many thanks for letter and enclosure. Contents noted.

W. A., Civil Engineer.—We have forwarded your communication to the proper quarters. We will insert any *short* letter in which you prove your priority of the invention of *end grain wood backings*, and of *flat-end shot punches.*

T. G. (Hull).—Declined.

J. H. (Huddersfield).—Personal vituperation is not argument, and, above all, not *scientific* argument. The *argumentum ad hominem* is always weak, but more especially so when discussing matters of science. We have the pleasure of knowing Mr. Z. C., the gentleman to whom you have alluded in terms that we will not characterize; he is a man of unquestioned talent, both practically and theoretically, and in all other respects he is very far from deserving your harsh expressions.—The very favourable opinions we entertain of the Richards' indicator have been founded on practical experience as to its merits. In conclusion, we hope that you will eliminate all personal feeling out of any communications you might wish us to insert.

W. S. E.—How much metal do you mean by writing a "small quantity of aluminium?" This is just about as definite as saying "a piece of cheese." The price of aluminium is now about 5s. an oz., in 1856 it was £3 an oz.; buttons and studs, &c., are thus sold for a few pence. You will find a great deal of new information about aluminium in pages 149 to 160 of the new "Dictionary of Chemistry," by H. Watts (Longman). As far as we can ascertain, the easiest and cheapest way for you to obtain a small quantity of aluminium for experimental purposes would be simply to buy one of the cheap ornaments of this metal that are generally sold in the shops. We may mention that the great expectations that were at first entertained about this substance have been rather dispelled. We believe that there is no known process of soldering it; the different small parts have thus to be rivetted together, and it also tarnishes very easily. It is noticeable that the inalterable qualities of any given metal are generally in a direct ratio to its density; the specific gravity of aluminium is only about 2·48. It is thus lighter than glass, and is only about one-fourth of the weight of silver, and its fusing point is also lower than that of silver. Common clay contains this metal to the extent of from 20 to 25 per cent., so that our houses may be said to be built of aluminium, or rather of alumina.

L. S. (London).—Mr. A. C. L. Devaux has taken out three patents for improvements in granaries for storing and preserving grain. No. 2486, 1s., in 1855; and Nos. 850, 1s. 4d., and 1087, 9d., in 1856. By sending these several sums in stamps, addressed to Mr. Bennet Woodcroft, Her Majesty's Patent Office, London, printed copies of the drawings and specifications will be forwarded to your address.

Correspondence.

SUBMARINE TELEGRAPHY.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

Sir,—In your impression of the 27th March are several letters bearing on a subject in which I have long taken much interest, that of Ocean Telegraphy; and as "H. K's." letter proposes a system of laying submarine cables which is, in my opinion, utterly impracticable, I shall ask you to allow me to make a few remarks on the reasons which have led me to such a conclusion. At the same time I shall endeavour to show "H. K." that I am not actuated by any prejudice against his plan, or for my own; but that as I am willing, nay, anxious, to hear all objections, so I claim the right to make them when necessary.

The question this writer professes to discuss is, as to where the cable should be laid—whether along the bottom or near the surface. I intend to show him that, first, it is not desirable to lay a cable at or near the surface; and, secondly, that if it were desirable, it is not possible by his method. Of course, to establish the second proposition would be sufficient, but I take this mode of argument because it is necessary to show what is and is not desirable, as well as what is or is not possible.

First, he assumes that if the cable were laid with "5 or 6 buoys" 20 or 30 fathoms under the surface, it would be accessible for repairs. As the buoys are under water it will be utterly impossible to find them by any other mode than grappling at right angles to the line in which the cable is known (or supposed) to have been laid. When he has had as much dredging and trawling in deep water as has fallen to my share during my surveying service, he will know how hazardous an operation this is. He will, probably, also find out that such men as Capt. Maury ought not to be pooh-poohed, and do not assert the existence of currents of all depths and in every part of the ocean without knowing perfectly what they are saying. If he will read Sir Edward Belcher's letters, he will find other and most important testimony in the same direction; and if my own experience may have any weight, I beg personally to assure him that at no depth, in no conceivable place, is there such a state as absolute stagnation of the ocean. In every part there will be some current; and in some parts, of a distance of 2,000 miles, there is sure to be a current, perhaps above, possibly below, of very considerable velocity. But, generally, we may affirm that the greater the depth, the less the disturbance probable from this cause at or near the bottom. However, as currents would evidently be fatal, "H. K." depreciates the probability of their existence; and after thus entering my protest, I am content to leave that part of the question.

We will then, for the purpose of argument, leave out the existence of currents, and assume that if the cable were laid on H. K.'s plan it would not be strained or moved by them.

Now, how are we to lay it? Each buoy will require its anchor and 2,000 (*circa*) fathoms of chain or wire rope, to keep it from coming to the surface. That is to say, six buoys and 12,000 fathoms of chain in all. In the middle of paying out, it may be in a gale, I am to stop and let go an anchor with 2,000 fathoms of chain (this will take about an hour in getting to the bottom), and then, if the cable is still in existence as a whole, I am to attach a buoy to it and let go. Three hundred and thirty miles from that spot I am to repeat the operation.

The result is, supposing all to go on as H. K. would have it, that at six points along the route the cable has to support twice the weight of itself in water at the particular depth, or, it may be, four miles length. I think the cable-makers would justly object to such treatment of their carefully-planned structure, even supposing that the difficulty of making the mooring strong enough could be overcome. Chain, which, merely for the sake of argument, I have supposed to be used, could not really, any more than a bar of iron, support two miles of itself in water for any length of time; and if steel wire were used, it would have to be protected from salt water as expensively as the cable itself. I need scarcely point out that this is a complication, not a simplification, of the process of deposition of submarine cables which it is most desirable to avoid. But, leaving out other objections which will occur to most seamen, as to the stowage, handling, &c., we now come to the reason why it is not possible.

Let "H. K." take a piece of water, 2,000 in. wide and 2 in. deep; let him lay a thread across it; now let him try, by supports at 300 in. apart, floating in the water, to keep it from touching the bottom—he may even try 30 in. apart, *i.e.*, 66 buoys instead of 6—and if then he does not renounce his scheme, I will attempt to convince him by some other reasoning.

He is quite right in appreciating highly the criticisms of "Old Sailor" on Dr. Wallich's plan. He only reproduces what many other seamen told the doctor before. As to its utter impracticability, I quite admit that "groundless assumptions are the bane of science;" and I fear that "H. K.," in trying to get off the ground and going out of his latitude, will find the truth of the assertion practically and personally demonstrated.

The letter of "Philo," in your columns, I cannot say I am surprised at. The manner in which he has told some most bitter truth may, and probably will, produce a great deal of annoyance; but those concerned should take it as a warning, that so much would not have been said in the case of a project which every one is anxious to see successful, by whomsoever undertaken, if there was not very great ground for dissatisfaction; and to the arguments used on the absence of the nautical element from all consulting committees, I have long given my hearty concurrence. The public is never satisfied if after failures in whatever undertaking, the causes of those failures, possible and probable, do not receive full elucidation, and are not shown to be carefully guarded against. Expressions, however confident, of satisfaction with the very means which probably contributed to those failures—a reliance, however childlike the faith which prompts it, on the adage, "Better luck next time,"—are not likely to be efficient in adducing that hearty support which a great national undertaking is entitled to expect and ought, under other circumstances, to receive. Nor will the highest names on the list of abstract science, the brightest promises of experiments in the future, be so attractive of national confidence as well regulated experiments made in the sight of all, for the benefit of all.

But it is said, Give us your money, and we will try any experiment you please. That cannot be. Your experiments must give confidence, and then the confidence will give you money.

For such experiments, properly conducted by men who have no other than a scientific interest in the question, I believe individuals would gladly subscribe money, and the Government might properly be asked for aid. They have already done something in this direction, and would probably do more, if it were to forward the general good rather than particular views. But there are many experiments which might be tried with little expense—so little as to be easily within reach of the influential moneyed supporters of submarine telegraphy, if only there were among them that united action which must be arrived at before we can expect any great successes. All who were interested in the matter hoped to have seen a committee appointed, not by any company, but by the scientific bodies; before whom all the questions could have been fairly brought and dispassionately argued, in which all the elements of science concerned should be fairly represented, and at which no man should sit by virtue of any other title than his knowledge of some branch of the subject.

The mode of action should not be, in my humble opinion, as in the last Government committee, to ask general questions, but to take each separate proposal, and thoroughly, and by examination of all who were willing to give evidence on that particular subject, to bring out the fact that it was, or was not, worth a practical trial. Take, for instance, a particular cable, hear *pro* and *con*, strike the balance, and decide how it shall be tried, or whether it is worth while to try, on which side truth rests—whether the advocates of the idea are sensible men, or its opponents right in their objections; gradually, even slowly it is true, but surely, would fallacies be thus struck down, and true theory receive its confirmation.

Many points have already been settled, and only require authoritative enunciation. For myself I do not fear—rather, I court such a test. For though I am like all of woman born, personally desirous of success, I am still more desirous that the truth may succeed, and only in so far as I believe in the truth of what I advocate am I anxious for its adoption.

It is because I feel thus—because I believe that truth is the one thing to be disinterred from the mass of error, not to say misstatement, which has done so much to impede the progress of telegraphy—that I cannot but admire the reasoning of "Philo's" letter. Of its agreeability there are, no doubt, two opinions; of its ability there can be but one; and however rough the operation, it is the part of a true friend, to lay bare error, to rub vigorously the frost-bitten feature. All I can say is, that, whenever any one is kind enough to undertake the operation for my benefit, I am duly grateful. I can get many who will applaud success and make things pleasant —very few who will be at the trouble to point out error—still fewer who will help one to a way out of it.

J. H. Selwyn, Capt. R.N.

AN ATLANTIC TELEGRAPH.

Sir,—Having shown in my last communication that, in ocean telegraphy, laying the cable near the surface is to be preferred, and having pointed out what appears to be the best mode of doing so, I shall now proceed to consider the question—what is the best telegraphic route from Britain to America? And, in doing so, it must be altogether unnecessary to enlarge on the importance of a right settlement of this question—apart from all personal considerations or local prejudices—because we must all be perfectly conscious that, if by any want of judiciousness in any respect, a second cable should be laid, and should it fail to work, it will have a most disastrous effect in postponing telegraphic communication with America *sine die*.

Whatever the routes may have been which have been suggested, the two following seem to be preferable to all others—namely, that by Ireland to Newfoundland, to be herein termed the southern; and that by Scotland, Ireland, and the south point of Greenland to Newfoundland or Labrador, to be termed the northern. The latter, it may be mentioned, was originally proposed by the writer; and the terminus in Newfoundland is preferable to one in Labrador, for reasons to be afterwards assigned. The election thus lying between these two routes, it is further believed that, if the decision turns—as it is thought it certainly ought to do—upon the question, which line would be most easily and cheaply, and least riskfully constructed and laid, would work most efficiently and pay best, and would be attended with least risk in all other respects, the northern is superior to the southern, and deserves to be preferred on the following grounds:—

The northern route being divided into three sections, the cable could be made and laid section by section, and no more than one section need be so made and laid until such section was first seen to work; and being found to work it would necessarily impart the utmost confidence as to the working of the other two sections when these should also be made and laid; and the working of the three *separately* would imply, as a matter of course, the working and success of the whole line. Now, all these vastly important results, arising from the laying and working of the first section only, could be obtained by the expenditure of a very small amount of capital, not even so much, it is believed, as £100,000. And the north cable being thus made sectionally, it would, if anything, be better made; and being laid sectionally it would, beyond all doubt, be laid so much the more easily and cheaply, and with much less risk; for in laying the separate sections, ships of much less size, and also much less time, would be required than on laying the whole cable at once, thus also diminishing the danger from storms, from which, it will be recollected, the "Agamemnon" and "Niagara" suffered so much in laying the former continuous southern cable.

Again, by the north route being divided into sections, it is well known that messages could be transmitted much more quickly, much more certainly, and much more constantly, than by the long continuous southern line—supposing the latter did work to some extent. Further, when the sections are laid, if any injury should happen to any one of them, it would be confined to that section alone, and in that case the injury would be much more easily, cheaply, and expeditiously repaired than it would be in the case of one long continuous line like the southern.

The superiority of the north line over the south, in every essential point, is thus seen to be most manifest, and that upon plain, unexaggerated, and most conclusive grounds. But we shall now proceed to consider what are the advantages of the south line. And these, it may perhaps be asserted, are four—namely, it would be 200 or 300 miles shorter than the north line; it would have fewer shore ends; it would not be directly connected with any other than British and colonial territory; and it may be said it would be less liable to danger from ice.

Assuming, in the meantime, that all these advantages are in favour of the south route, they do not nearly counterbalance the essential and important advantages of the north, as above set forth. But, in point of fact, a less distance of 200 or 300 miles is no advantage whatever, if the enterprize, from its consequent great continuous length, is of the most doubtful success, and is attended with extremely great and constant risk. Again, its greater number of shore ends would enable the north cable to perform its work far better than the south—supposing the south, under all its disadvantages, to work at all, or for more than a few weeks, that being the whole extent of the working of the former south cable. And though the south cable would not touch other than British and colonial, while the north cable would at two points touch Danish, territory, that is surely not an objection to be listened to in this age. On the Continent, railroads and telegraphs run in all directions through different kingdoms. And if the north line is constructed by the British Government, with special reference to Britain and its colonies, the line would, of course, be entirely under its control, though affording the utmost amount of accommodation possible to all others who would be requiring and would pay for its use. Again, as regards the south line being less liable to danger from ice, this is a mistake; for it is liable to be visited at its western terminus by icebergs. But if proper and easily-adopted precautions are taken in landing the north cable at or about Cape Farewell, in Greenland, and if it is then made to run to Newfoundland, and is landed there under similar precautions, it is believed, after most careful consultation of the best authorities, that all danger from ice would be altogether avoided. But if the line were conveyed to Labrador, it would there, no doubt, run the greatest danger from ice, as the north-east winds, prevalent in that quarter, bring down the icebergs from high northern latitudes, and drive them against, and accumulate them in great masses, upon the Labrador shore. Besides, the cable, by being landed in Newfoundland would reach the inhabited parts of America much sooner than if it were carried to Labrador. It is therefore, to be hoped that, in respect to the landing of the north line in Newfoundland, the interests of Europe and America will not be sacrificed to the paltry impotent rivalries of private companies or private individuals. If they are unable to do any good, we will do them the justice of believing that they will not attempt to do evil, and to become wretched obstructives.

On the whole of the grounds now submitted, it is thought that nothing could be clearer in science, in reason, or in ordinary commercial rules, than that the northern route, as now pointed out, should be preferred, and that more particularly on the extremely important ground of its admitting of the telegraph cable being made and laid, section by section, as already adverted to. I may add that it may, with great confidence, be expected that, by the adoption of surface telegraphy, the south line will also yet be made, and will be found to work with permanence; but even though this confidence should exist, it would be most unwise to adopt this course in the meantime, encountering very great unnecessary risk, when another course is open attended with far less risk. It need scarcely be said that to encounter great unnecessary risk, especially in important matters, is a course utterly opposed to science, reason, and sound commercial principles, and is, in truth, a sign of the most childish folly—if it should not be called by a harsher name—when we ask others to peril their money in connection with such risk.

It may, in conclusion, be mentioned that the writer, in penning the preceding remarks, is perfectly impartial, as he has no peculiar interest whatever in any of the routes beyond what the facts justify and require. His sole desire is that a work so great, so honourable, and so useful as a working telegraph to America would undoubtedly be—one that would affect so beneficially the Empire and the World —may, by the adoption of the very best means in our power, be speedily accomplished, and be crowned with complete and permanent success. But if we do not adopt the very best means in our power, we we are not entitled to expect nor even to deserve success, but, on the contrary, must lay our account with disaster and failure and all its evil consequences, together also with disgrace; for, while there is no disgrace, but the highest honour, in failing in a noble cause, where we have neglected none of the means in our power to ensure success, and have so calculated the matter as not to put it in the power of any to gainsay, it is altogether different when we act in an inconsiderate manner, and foolhardily encounter the most unnecessary risks. And let it always be kept in view that this, in reality, is not a mere trifling private company or individual—it is a national and an imperial affair, in which the national and imperial character and interests are thoroughly and deeply involved.

Edinburgh,
3rd April, 1863.

H. K.

Miscellanea.

M. Dollfus reports to the *Societe Industrielle* of Mulhouse his success in using the heavy oil extracted by M. Lebal from the asphaltum and bitumen, at Pechelbronn. He says that it is perfectly successful and very economical as an unguent for heavy machinery. He applied it to the inner surface of his boilers and heaters by warming them so as to make the oil more fluid, and then applying it in a thin coat by means of a common broom. The results were very satisfactory; the calcareous crusts were gradually detached and the metal everywhere exposed. "I continue to use the oil whenever I clean a boiler, and I judge that the expense, which which is about 10 kilos. (20 lb.) for a boiler of 45-horse power, is largely compensated for by the economy of fuel in consequence of the metal being clean; repairs are also much less frequent, as the boilers do not burn out so freely."—*Bulletin de la Societe Industrielle de Mulhouse.*

Yellow spots on leather frequently occur, and these detract from its value. A correspondent of the *Shoe and Leather Reporter* says they are caused by decomposition in the hide, probably in the sweating process. The remedy, he says, is "more care in the manipulation or working of the hides. With good, cold spring water for soaking, and with a sweat-pit kept at the right temperature, with ice or otherwise, and a cool, sweet liquor for the first stages of handling, there is but little danger of being troubled with yellow spots on leather."

It has often been a subject of remark and surprise that some plan is not devised so lessen the breakage of coal in the transit from the truck to the hold of the vessel. Many of the Monmouthshire veins are so friable and tender that when a cargo arrives in Ireland, it is often found that the brash or small coal is 25 per cent. of the total. This, as may be imagined, is a serious loss, and the breakage is principally caused in connection with the shipping. The agent of the Cork Steam Company is said to have invented a plan, by means of a tube peculiarly constructed, which will greatly reduce the breakage. The coal is conveyed through this tube to the hold of the vessel, and it is found that the average small is reduced to from 2 per cent. The tube is now exclusively employed in loading on the Cork wharf.

On Wednesday last some trials took place at Chatham dockyard in the presence of several of the heads of departments at that establishment to test the lifting powers of a new description of pulley, designed in the first place by Mr. Moore, of Bristol, and some years after patented by Mr. Weston, and now manufactured in Birmingham for the firm of Messrs. Shepherd, Ransome, and Co. The pulley tested on Thursday was one calculated to raise weights under four tons, and that with less than half the power required under the ordinary arrangement of blocks, as used in the dockyard. The pulley was suspended from one of the cranes, and the "endless" chain attached to one of the four-ton iron armour plates just landed. The ropes, or rather circular rope, attached to the pulley were then taken in hand by four men, and in half a dozen turns of the wheel, and without any undue exertion on the part of the workmen, the slab was hoisted to the required height. Another ton weight of iron was then added, and the large wheel which sets the pulley in motion again made to revolve, when five men in a few turns raised the slab and the additional pigs of iron, the whole being held in its place without any need of men retaining their hold on the rope.

The ironmongers' meetings for the current quarter commenced at Wolverhampton on Wednesday last. The attendance was comparatively small, and the amount of business transacted was limited. Even in pig iron, which generally forms the staple business of the Wolverhampton meeting, the transactions reported were less than usual; and for the manufactured commodity there has been a fall-off in the demand for the last two or three weeks, and it is only the principal firms who have sufficient orders in to keep their works in full operation; so far as they are concerned, prices are steadily adhered to. Another class of makers are not getting such good prices as at last quarter-day. The pig masters are suffering from the high price of ironstone, the yield of the district; for every description there is a good demand; its increasing scarcity is becoming more felt, and those who raise it are endeavouring to obtain higher prices, which consumers are unwilling to yield to; the market price of Staffordshire pig-iron being such as to prohibit any further rise in the price of materials, the more especially as the pig masters have to encounter increasing competition with their brethren in the trade in North Staffordshire, also with the Forest of Dean and the Cleveland Districts. The sales of "pig" reported at this meeting were at much the same prices as last quarter-day, but there was less buoyancy than on that occasion, and this branch is not nearly in so satisfactory a state as could be desired. There has been some degree of uneasiness in the trade during the week, consequent on the notice given by the puddlers for an advance in their wages scale. These expired last Saturday, and in some of the works the men have not yet gone in; but it is not anticipated that this demand will be persisted in, and that at latest all the men will have resumed work by next Monday or Tuesday. The state of the trade is not such as to admit of any advance, and on the part of the masters there exists a firm determination not to yield any. The great meeting of the trade will take place, as usual, in the Town-hall, Birmingham, on Thursday.

At a recent meeting of the Microscopical Section of the Manchester Literary and Philosophical Society, Mr. Charles O'Neill exhibited a mounted fibre of Orleans cotton, torn by a gradually increasing weight suspended to its extremity. It had sustained a weight of 162 grains for many minutes. Mr. O'Niell stated that there were 143 such fibres in ·01 grains of cotton, each fibre therefore weighing less than the ten thousandth part of a grain. The strongest fibres were capable of supporting more than two million times their own weight. He is engaged in making experiments upon the tensile strengths of various fibres by a special apparatus, but they are not yet completed.

Westminster Bridge.—From a Parliamentary return, published in December, 1862, the amount expended on the works connected with this bridge was—

To contractors	£145,057	18	5
To other parties	248,132	0	9
Making a total of	393,189	19	2

The length is 1,160 ft. 3 in., and the width between the parapets 84 ft. 2 in. The cost would therefore be £338 15s. per foot run, or about £4 per foot superficial, whereas, in the late Sir William Molesworth's report, the estimated cost was stated to be £235,000, or £2 8s. 6d. per foot superficial. In addition to the sum of £393,189 19s. 2d., there has been £109,054 4s. 9d. paid for approaches. The whole amount has been supplied from property belonging to the Westminster Bridge Commissioners and Votes of Parliament.—*A Record of the Progress of Modern Engineering*, by W. Humber.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

The Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

Steam Engines, &c., 2499, 2503, 2536.
Boilers and Furnaces—*none.*
Roads and Vehicles, including railway plant and carriages, saddlery and harness, &c., 2515, 2517.
Ships and Boats, including their fittings, 2533.
Cultivation of the Soil, including agricultural implements and machines, 2501, 2521.
Food and Beverages, including apparatus for preparing food for men and animals, 2491.
Fibrous Fabrics, including machinery for treating fibres, pulp, paper, &c., 2504, 2507, 2519, 2523, 2532.
Buildings and Building Materials—*none.*
Lighting, Heating, and Ventilating, 2528, 2529, 2534.
Furniture and Apparel, including household utensils, time-keepers, jewellery, musical instruments, &c., 2497, 2509, 2512, 2513, 2536.
Metals, including apparatus for their manufacture, 2510, 2511, 2516, 2518, 2620, 2524, 2527.
Chemistry and Photography, 2535.
Electrical Apparatus, 2508.
Warfare, 2495, 2506, 2530.
Letter-Press Printing, 2498, 2514.
Miscellaneous, 2492, 2493, 2502, 2522, 2525, 2526, 2531.

2479. J. Maurice. *Improvements in the construction and preservation of ships and vessels.* Dated September 9, 1862.

This invention consists in forming round the sides of a ship or vessel, or attaching to the outside thereof, a solid, or hollow belt, which may be divided transversely as well longitudinally, and should be fixed about the light-load water line, to give increased buoyancy or ability to carry armour plating for vessels of war, or to enable ships to carry additional weight applied externally or internally, whether such ships be for commercial or war purposes. *Patent abandoned.*

2480. J. F. Selby. *Improvements in traction engines and in valves for traction engines where compound engines are used, which latter improvements are applicable to compound engines generally.* Dated September 9, 1862.

These improvements in traction engines relate to such traction engines as are driven by cog or spur wheels, which wheels are usually allowed to vibrate with the spring of the engine to a certain extent, thus creating great wear and tear and loss of power, by the constant jolting and vibrating of the wheels. This great objection is obviated in the present improvements, which consist in forming the axle of the driving wheels in three parts, connected together by what is generally known as Hook's joint, or by any other suitable joint. The centre and shortest length (which has on the middle of it the cog wheel or wheels) is held up and supported in framing, or between two brackets or bearings, and thus revolves constantly in the same position geared into the cog or spur wheel or wheels of the crank shaft. This position of the wheels is not altered however great the jolting of the engine or vibration of the springs. The Hook's joints are fixed on to the ends of this short part of the shaft outside the brackets or bearing, and connected on to the other two lengths of the shafting respectively, on which the driving wheels are placed in the usual manner. The improvements in valves relate to compound engines whether employed in traction engines or otherwise, and consist in constructing the slide valve ports, steam chests, and chambers so as to regulate the admission and exit to and from the cylinders as may be required. The cylinders can be placed one within the other (the outer one therefore being an annular cylinder), or they may be placed side by side or in any other position found most convenient. The pistons and rods may be connected together (in the usual way) to one crank, or they may be conneced to separate cranks, and the cranks may be fixed either in the same or in opposite directions, or at right angles, or any desired angle to each other, or indeed in any position desired. *Patent completed.*

2481. W. Hirst. *Improvements in machinery to be employed in the manufacture of paper or linen spool tubes, which machinery is also applicable for the manufacture of cartridge cases.* Dated September 9, 1862.

We cannot here give space to the details of this invention. *Patent completed.*

2482. J. Walker. *Improvements in the manufacture of oil presses.* Dated September 9, 1862.

According to this invention, the inventor proposes to enable the presses to be worked independently of each other by means of an improvement in the junction pipes or passages, whereby the oil may be shut off when desired from or between either of the presses, so that one press may rise while the other falls, or so that one may be kept stationary while the other is rising or falling. *Patent abandoned.*

2483. T. Fleitmann. *Improvements in the manufactare of copper from copper ores..* Dated September 9, 1862.

This invention is more particularly applicable in the manufacture of copper from those ores which contain silver or gold, and which have as impurities arsenic, antimony, and phosphorous, which, according to the ordinary roasting and smelting process, are very difficult to separate entirely from the copper. The copper ores employed are first ground to a powder, then part of such powder is subjected to a roasting process, and is roasted dead. The roasted product is mixed with the unroasted portions of the ore, and together with suitable materials for producing a slag, such as silica, and cinder of a previous smelting process; it is then subjected to heat in order to be melted. The melted mass is run into water, and the product is ground to powder. Part of this powder is subjected to a roasting process, and is roasted dead. The unroasted and roasted products are then mixed, and together with fluxing materials, such as silica and cinder or slag from a previous smelting process, are subjected to heat and melted. The melted mass is run into water and again ground into powder. The powder thus obtained when necessary is divided into two equal parts, one of which is roasted dead and then mixed with the unroasted powder, and the mixture is melted as before. In this manner the ore is again and again treated till the resulting sulphuret of copper is in the condition desired. The sulphuret of copper obtained is ground to a powder, is roasted dead, and moistened with a solution with an alkali, for which either carbonate or caustic soda or potash is used. In those cases where the quantity of silver or gold present is important, then the same is to be extracted in the ordinary manner before roasting the sulphuret of copper dead. The oxide of copper is subjected to heat so as to melt the alkali, but not the oxide of copper, which is then to be well washed in water. The product obtained is mixed with powdered carbon (wood charcoal being preferred) and then melted, applying either coal or carburetted hydrogen or pure hydrogen, which is preferred to be done in a blast furnace of comparatively small height, the interior of which is lined with fire brick or fire clay. *Patent abandoned.*

2484. J. Saunders. *Improvements in lamps.* Dated September 10, 1862.

The patentee claims the construction and use of lamps having annular reservoirs, which are combined or connected by means of a central arrangement of syphons and air tubes with a wick receptacle or cup of any convenient form or size, as described. *Patent completed.*

2485. J. Saunders. *A new or improved railway break.* Dated September 10, 1862.

The patentee describes this invention as a simple, inexpensive, continuous railway break, to be made to act by the power of the locomotive, and requiring no fixing between the carriages, but ready to act upon the carriages being screwed up together as is usual. The details are too voluminous to be given here. *Patent completed.*

2486. M. Smith. *Improvements in machinery for raising the nap on woven fabrics.* (A communication.) Dated September 10, 1862.

This invention consists in an improved combination and arrangement of machinery combined with heating cylinders for raising the nap on cotton or other woven fabrics. The fabric to be operated upon first passes between stretching bars, then over a heated cylinder, then over and under other stretching bars between which the surface of the fabric is presented to the action of rollers covered with card teeth, or other agents for raising the nap. The fabric is then taken over another heated cylinder, and under and over other stretching bars, between which are other raising rollers; drag rollers are also provided at intervals to keep the fabric to the requisite tension. The number of heating cylinders, raising rollers, drag rollers, and stretching bars may be increased or diminished according to the nature of the fabric to be operated on, and to the finish required. The drying and warming of the fabric during the operation render the fibres more susceptible to the action of the raising cards or other agents. *Patent completed.*

2487. W. Rothera. *Improvements in machinery or apparatus for rivetting boiler plates, tanks, and similar articles.* Dated September 10, 1862.

This invention is carried out as follows:—Upon a suitable cast-iron frame the patentee places a ram in sections, and a shaft with cams and eccentrics upon it, so as to push one section of the ram upon the boiler plates, and hold them together until the other part of the cam or eccentric pushes up the interior of the ram against the rivet, and completes the rivet, or presses it to its place. At the back part of the machine, he puts two large levers which press against the pedestals of the cam or eccentric shaft, and hold them in their places until the pressure is put upon the plates, which at this point of the action presses back the pedestals of the cam or eccentric shaft, and slightly raises the levers. Upon each lever are suspended two large weights, one of which rests on a cast-iron bed or frame, and the other is always suspended upon the lever which determines the pressure which is put upon the plates. In pushing up the rivet which is performed in the same revolution of the machine, the pedestals of the cam or eccentric shaft are pressed a little further back, which raises the levers a little more, carrying all the weights along with them, and thus putting more pressure upon the rivet than it does upon the plates. Or the machine may be made, along with these motions before stated, to have a shaft put up inside the dolly or holder-up with an eccentric, so as to have a motion at both sides of the plates. He also causes the plates to be held tightly together, and the rivet rivetted or clenched up at the same time, by employing suitable cast-iron frames; and he places upon them two steam-cylinders and pistons and rods, one set beyond the other, so that the back rod intended for the rivet shall work through the front rod, which is intended for the plates, the rod being pressed against the plates, holding them tightly together until the back one comes up and presses the rivet up. *Patent completed.*

2488. H. Hands and H. Holland. *New or improved compositions for the manufacture of black ornaments, such as brooches, bracelets, ear-rings, and other ornaments usually made of jet, which said compositions may also be applied to the manufacture of various other articles.* Dated September 10, 1862.

This invention consists of the compositions hereinafter described, which compositions resemble jet, and may be used for the manufacture of the articles commonly made of jet, as well as other articles commonly made of ebony or other black material or composition. In making a composition to be used in the manufacture of black ornaments and other articles usually made of jet, the patentees take jet or scrap jet and reduce it to a very fine powder. They mix the said powdered jet with varnish and india-rubber and gum in a certain manner, so as to make a plastic material which may be moulded into any required form. *Patent completed.*

2489. J. Vigouroux. *An inoxydable white metal suitable for making taps or cocks and other useful articles.* Dated September 10, 1862.

Here the patentee obtains an inoxydable metal of a sort of steel white, of a high grain, capable of a high polish, and of becoming an ornamental metal, by combining antimony and nickel, and giving them tin for a basis. *Patent completed.*

2490. A. Barclay. *Improvements in traction engines, and in apparatus for indicating the pressure of steam.* Dated September 10, 1862.

This invention has reference to a previous patent, dated March 10, 1862 (No. 646). Under one modification of the present invention as applied to traction engines of the "right-angled class," the crank-shaft of each pair of engines has its bearings at one end arranged in the side standard or frame, whilst the other end is connected to the main axle, or to the centre of the driving wheel, so that this end of the shaft vibrates with the motion of the spring of the driving wheel, whilst the other end remains a fixture in its bearing. The other pair of engines has its crank-shaft arranged in like manner, the fixed bearings being on opposite sides of the machine. In this way the vibrating motion of the wheels as they traverse over the inequalities of the road is imparted to one extremity of each crank-shaft, but without affecting the opposite ends which revolve steadily in their bearings. The object of the arrangement is to prevent the vibration of the driving wheels from affecting the beat of the valves. *Patent abandoned.*

2491. G. Ritchie. *Improvements in extracting the liquid portion of yeast, spent hops, or other similar matters, and in the apparatus employed therein.* Dated September 10, 1862.

This relates to a mode of subjecting yeast, spent hops, or other similar matters, to filtration, so as to extract therefrom the liquid portion. Under one system of arrangement, the yeast obtained in brewing is placed in a filtering vessel, which may be formed either of metal. stone, slate, or wood, coated to render it impervious to air. Inside the filtering vessel is fitted a false bottom. This false bottom is properly fitted in its place, and the space between it and the filtering vessel is put in communication with an air-pump. On the surface of the false bottom two, three, or more piles of filtering cloths are placed, and the yeast is then poured on to the cloths. The air is exhausted from beneath the false bottom by the air-pump, the atmospheric pressure on the upper surface causing the fluid portion of the yeast to be driven rapidly down through the interstices of the cloths and the false bottom. In this way the whole of the liquid portion of the yeast is utilized and an important saving effected. *Patent completed.*

2492. G. T. Bousfield. *Improvements in machinery used in the manufacture of files.* (A communication.) Dated September 10, 1862.

The first part of this consists in an improved method of holding the file blank which is to be cut up to the face-plate near which the cutter strikes, so that, if the face of the blank be not true, the bed in which the blank is held may accommodate itself and present that portion of the blank which is operated on squarely to the cutter. The second part consists in a device for regulating the blow of the cutter, so that it may strike harder on the wide part of the plank than on the narrow part, where less force is required to make a cut of equal depth; the third, in an improvement in the face place. *Patent completed.*

2493. A. Rigg, *jun.* *Improvements in apparatus for carrying and tipping coal and other minerals, and in steam brakes used therewith, and with other machinery.* Dated September 10, 1862.

This consists of a platform sustained on axles or rollers which carries the waggon or other receptacle containing substances to be upset, the centre of motion being so adjusted that, when full, the weight of minerals overturns the whole, and when empty returns to the original position, unless otherwise restrained. Towards that portion of the waggon which descends lowest in overturning is fixed a riddle, moveable with the machine, and attached to it at any angle either curved or straight. For the the larger series of machines, the patentee prefers steam brake which possess a cylinder closed at both ends, and a large passage communicates steam to the upper or impelling side, and a smaller opening supplies the lower or retreating side, and to this side is connected a large escape tap or valve, to be regulated at will; or the inlet to the lower side thereof may be made to reduce as the exhaust or escape valve opens. *Patent completed.*

2494. G. T. Bousfield. *Improvements in machinery for cutting files.* (A communication.) Dated September 10, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2495. W. A. Munn. *An improved apparatus for capping, loading, and closing cartridges for breech-loading firearms.* Dated September 11, 1832.

This invention is not described apart from the drawings. *Patent completed.*

2496. T. Steel. *Improvements in treating soap suds or other saponaceous or oily matters.* Dated September 11, 1862.

This consists in the use of a perforated vessel, in which the inventor first subjects the "magmire" to the action of steam, whereby the lighter parts of the oily or greasy matters are carried off, and the magmire becomes heated and prepared for being placed in the press to extract the residue of oily or greasy matters by pressure. *Patent abandoned.*

2497. G. Weeks. *Improvements in constructing frames, trays, pots, or holders for flowers, plants, or shrubs, growing or otherwise, with arrangements for their display, and also for drainage.* Dated September 11, 1862.

This consists in constructing these frames, trays, &c., with a hollow stand, pedestal, or support, which shall or may raise them at a convenient height above the table or ground, and shall serve as a reservoir or receptacle for the water with which they may be watered to drain into; and also in constructing them with a hollow chamber or passage for water, formed entirely or principally of a pair of plates or thicknesses of metal or porcelain, &c., which may be parallel to each other or not, the lower one being so dished or inclined as to drain or flow off the water into the reservoir above mentioned, and the upper one having perforations, through which the water may pass, and also having partitions upon it for separating the flowers, &c. *Patent completed.*

2498. C. H. Humphrey. *Improvements in printing machinery.* Dated September 11, 1862.

This consists in the mode of raising, guiding, and lowering the printing roller during the backward and forward motion of the horizontal table. For this purpose, the inventor employs a pin projecting from one end of the printing roller, which pin, as the roller revolves, is caused to take into a curved slot or guide fixed on one of the upright brackets which carry the bearings of the axis of the printing roller, and as the pin advances up this curved slot or guide, the printing roller is raised and guided out of gear with the horizontal table, and when the pin arrives at the highest point of the curved slot or guide, it is caused to remain there until the horizontal table arrives at a certain relative position, when it is lowered down vertically and into gear again with the table. With this arrangement for raising, guiding, and lowering the printing roller, the bearings of the axis of the said roller have a reciprocating vertical motion imparted to them, and the result of the improvement is that the machine is caused to register with greater accuracy than hitherto. The other improvement consists in an arrangement for guiding the horizontal table more accurately than heretofore. *Patent abandoned.*

2499. F. Daticky. *Improvements in steam engines.* Dated September 11, 1862.

This invention consists of an apparatus which the inventor connects to steam engines, and to the boiler or boilers of such engines, for the purpose of assisting in creating a vacuum behind the piston, of utilizing the escape or waste steam, and of condensing it and returning it to the boiler. He connects to the boiler a cylinder for receiving steam direct from the boiler; this cylinder is in the form of an inverted cone at bottom, and has fitted in it a piston, terminating in a conical foot, which corresponds with and enters the conical bottom of the cylinder. At top the piston has a regulating screw, whereby it may be raised more or less up in the cone, and so allow of the issue of steam from the cylinder being regulated. This cylinder is fitted in a larger cylinder, into which the escape steam is free to enter, the outlet from this outer cylinder is narrowed, and leads into a condensing chamber, in which also the conical bottom of the first-mentioned cylinder is made to enter. The condensing chamber is fitted with four or more valves for the admission of air. Opposite the conical bottom of the steam engine, and in the condensing chamber, there is a conical vessel with a bell mouth, in which a corresponding conical plug is fixed. Like the piston, the position of the plug can be regulated to allow of the outlet being increased or diminished; the conical vessel leads into a conduit for conveying the water to be fed into the boiler. The action is as follows:—Steam from the boiler being admitted into the conical bottom cylinder, and escape steam into the cylinder surrounding it, the steam issuing from the conical bottom of the cylinder creates a blast, which draws in the escape steam from the steam engine into the condensing chamber, and at the same time air through the valves in the chamber, the steam in the chamber becomes condensed, and passes off through the conical vessel and conduits to be fed into the boiler. *Patent abandoned.*

2500. J. Hemsley. *An improved fabric or material for scarfs, ties, handkerchiefs, and neckerchiefs.* Dated September 11, 1862.

This improved material is a looped silk fabric, which the patentee ornaments by printing with spots, sprays, or with any other desired design, pattern, or device. The intended article is produced in the frame of its proper size, or the article may be cut from the piece. *Patent completed.*

2501. R. A. Brooman. *Improvements in implements for cultivating the soil.* (A communication.) Dated September 11, 1862.

This invention relates to steam tillage, and consists of an implement composed of two main parts: the first, intended to cut out the earth vertically, is in the form of a rectangular box without any bottom; three of its sides are cutting, for the purpose of penetrating, on pressure being applied, into the soil to the depth required. The second main part consists of one or more screws set to bore down into the soil within the space encompassed by the box; on being raised the screws turn over the soil, and transfer it into a furrow at the back of the box. The implement advances, the box is inserted into fresh ground, the screws descend, and, on ascending, take up soil and turn it over into the furrow last formed by them, and so on. *Patent completed.*

2502. W. Clark. *Improvements in cigar and cigarette cases.* (A communication.) Dated September 11, 1862.

The distinctive feature of this new kind of cigar holder consists of a case closed at one end and furnished at one part (the side, or either end, for example) with a small frame with hinges, similar to those used in purses, this opening frame extending only on one end or side or part of the case. *Patent completed.*

2503. L. C. Hoyau. *An improved portable apparatus for marking time, to be called "a memento bijou."* Dated September 11, 1862.

This consists in the construction of a portable apparatus or jewel, which the patentee calls more particularly under the name of indicating marker or memento bijou, the object being to assist in remembering the date, the day, the month, or the year, and also, if necessary, the exact hour and minute of an appointment, and, in short, under all circumstances where these dates may be found useful. It consists of six wheels or rotating circular dials, on the lateral circumference of each of which are respectively marked the indications to be read off. The apparatus can be made of any form and of all sizes. In varying the form —which may be circular instead of elliptical—it can be made to represent a seal with or without engravings, a brellock or a medallion, on which can be placed a portrait of any other object, in the free space, in the openings through which the figures or indications are seen; it can be made of metal, and covered with magnifying glasses, by which the indications can be more plainly seen. *Patent completed.*

2504. J. Thomson. *Improvements in the treatment of vegetable fibres with a view to their manufacture into textile fabrics.* Dated September 11, 1862.

This relates to a combination of certain chèmical and mechanical processes for treating vegetable fibres, whereby such fibres can be made to resemble the fibre or staple of cotton, wool, or silk, and become better adapted to the manufacture of textile fabrics, either by themselves, or mixed with other and more costly materials. *Patent completed.*

2505. A. Barclay. *Improvements in locomotive boring and winding engines.* Dated September 11, 1862.

This relates to the arrangement and construction of boring and winding engines, which are also arranged to be self-propelling. Under one modification the boiler of the engine forms the framing, or it may be carried on a rectangular framing in the ordinary way. The boiler is of the horizontal tubular class, and on the upper part is arranged a pair of standards which carry a horizontal shaft forming the axis of a beam; one end of this beam is connected to the piston rods of a pair of vertical cylinders placed on the upper part of the boiler at one end. The other end of the beam overhangs the end of the engine, and to this free extremity are attached the boring rods and tool. A horizontal cylinder is arranged parallel with the boiler on each side; the piston rods of these cylinders are connected to a crank shaft extending across the boiler. A pinion on the crank shaft drives a spur wheel on a shaft fitted between the beam standards and carrying the winding barrel; this pinion slides to and fro on a feather, so that the winding barrel may be readily thrown into and out of gear by a coupling and hand lever. The crank shaft also carries a pinion or spur at each end, which gears with an annular wheel formed inside each of the main or driving wheels of the engine, so that, by putting these engines into gear with the bearing wheels, the engine becomes a traction engine. *Patent abandoned.*

2506. W. Richards. *Improvements in firearms and cartridges.* Dated September 11, 1862.

In constructing breech-loading fowling pieces and other small firearms where the barrels are mounted, so as to turn on horizontal axles under their breech ends, as in breech-loading fowling pieces of ordinary construction, the patentee uses, in order to lock the barrels in position for firing, a self-acting spring catch or bolt, taking into a notch in a piece projecting from the upper part of the breech end of the barrels; this piece as the breeches are closed for firing, enters a recess in the top or the breech plate or false breech the recess and the piece entering it are both inclined so as to draw the breeches tightly against the breech plate. The spring catch is mounted in the tang of the breech plate by preference, so as to slide longitudinally therein, a spring tending constantly to throw it forwards; in closing the breeches of the barrels, however, it recedes, both it and the piece at the breech end of the barrels being suitably inclined; immediately the barrels are closed it again springs forward into its recess, and so holds the barrels securely. The catch is drawn back to open the breeches by a thumb-piece on the top of the stock. *Patent completed.*

2507. J. and F. Walker. *Improvements in machinery for combing and carding or hackling flax, silk, wool, and other fibrous substances.* Dated September 11, 1862.

This relates to the machine known as Pseller's combing machine, and consists, under one modification, in causing the frame carrying the combs to revolve, so that the teeth of the combs may strike upwards or downwards into the ends of slivers, which, proceeding from the feed rollers, project over the edge of a table or bridge; and the patentees place above or below the bridge on which the slivers rest an axis, having arms projecting from it upon which brushes are carried. These brushes are of sufficient length to extend across the slivers. As the axis which carries the brushes revolves, the brushes in turn come round to their highest or lowest position. The details of this invention are too voluminous to be given here *in extenso*. *Patent completed.*

2508. P. Ward. *Improvements in the manufacture of a double sulphide of calcium and sodium.* Dated September 11, 1862.

Here the patentee produces double sulphide of calcium and sodium from the substance known as soda ash waste. According to this invention he takes this substance when in a fresh state (as when exposed to the air it becomes decomposed, and is then not so suitable for any purpose), and he mixes it with sulphate of soda in suitable proportions, and heats the mixture so as to obtain a double sulphide of calcium and sodium. *Patent completed.*

2509. T. Molineux. *Improvements in pianoforte actions.* Dated September 11, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2510. A. Whytock. *Improvements in the construction of coated and uncoated sheet-iron boxes, and in the mode of, and apparatus for, straightening coated and uncoated sheet iron.* Dated September 11, 1862.

This consists—1, in straightening the sheets or plates of iron by passing them between a series of rollers having a rotary motion, and which, by friction of contact cause the plate to move in a serpentine or wavy line, the deflections of which will decrease as the sheet nears the last rollers of the series. The invention consists—2, in partially or wholly lining the sheet-iron boxes with wood, in order to prevent disfigurement by buckling and bruises. *Patent completed.*

2511. A. E. H. B. Butler. *Improvements in machinery for straightening and polishing cylindrical bars of iron and other metals.* Dated September 12, 1862.

After bars of iron or other metal have been rolled by pressing between grooved rollers in the ordinary way, they are generally crooked, and the surface is not perfectly smooth; now, in order to render them straight, and to polish or give a high finish to the surface, the patentee places them on leaving the grooved rollers between two rolls, the length of which must be equal to or rather exceed the length of the longest bar to be operated upon. Above the two rolls is a third roll, which is pressed down upon the bar. The rolls are caused to revolve rapidly, and in revolving they impart a rotary motion to the bar between them, thereby rendering it perfectly straight, and imparting a high finish to its surface. As soon as one bar has been operated upon, the top roll is raised by weighted levers or other equivalent; the finished bar is then removed, and another put in its place. The bars may be operated upon when cold, and the arrangement of gearing for driving the machinery may be modified. *Patent completed.*

2512. J. B. Smith. *Certain improvements in washing and mangling machines, applicable in part to steam dyeing, and to bleaching, to be styled the "Sensation washing and mangling machine."* Dated September 12, 1832.

This invention is not described apart from the drawings. *Patent completed.*

2513. J. Thom. *Improvements in mounting or fitting artificial teeth.* Dated September 12, 1862.

This invention is carried out as follows:—A model of the mouth to which the teeth are to be fitted having been taken in wax (or other plastic material), and the artificial teeth placed in their proper positions, a cast is taken therefrom in plaster of Paris in the usual manner. After the mould has been completed and become hard, the wax is removed, and its place supplied with india rubber and sulphur, which is heated to a temperature of about 330 deg. Fahr., when the india rubber becomes semi-fluid, and takes the form of the mould; at the same time it becomes vulcanized and hardened. In cooling, the vulcanized india rubber is found to shrink or become distorted from the original pattern, and therefore does not accurately fit the mouth from which the model was taken. In order to remedy this defect, and give the required accuracy to the artificial gum, the patentee submits it to the following additional and corrective process, which he claims as constituting his invention. Having trimmed the vulcanized india rubber, and made any necessary corrections thereto, he replaces it (the teeth being imbedded in their proper positions) in the plaster mould, within a metal collar of conical shape, which by means of a screw press brings the parts of the plaster mould in close contact with each other and with the vulcanized india rubber. While subjected to this pressure, he heats it to about 220 deg. Fahr., which so far softens the vulcanized india rubber as to cause it to conform itself strictly to the mould. In this state it is left to cool and harden; and being taken out it retains the form of the mould, and accurately fits the mouth from which the original model was taken. *Patent completed.*

2514. J. R. Johnson and J. S. Atkinson. *Improvements in machinery for manufacturing printing types.* Dated September 12, 1862.

This invention has reference to the patent granted to the present patentees on Dec. 13, 1859, No. 2,828. In the present improvements they maintain the principle thus laid down, but greatly simplify and improve the machine. 1, By connecting the second with the first machine by a continuous instead of a moveable tube, thus obviating the necessity of the type being touched in its transit from one to the other. 2, By placing the cutters for planing the dressed sides of the type horizontally instead of vertically, and in a line with and behind those for cutting out the foot, and by passing the type through the line of cutters thus arranged, so that the type has not to return, but is carried gradually past such cutters. 3, By placing the composing-stick in a line with and behind the above arrangement of cutters, so that the type is set up by the same motion which drives it through the cutters. 4, They also greatly facilitate the adjustment of the machine in changing from one body to another, by placing several parts of the machine upon packing pieces of the exact size of the body, by simply changing which the machinery is at once adjusted for that body. 5, They also render the machine easily adjustable for the different sorts of a fount, by making the letters themselves act as packing pieces for the separating of the two parts of the tube through which the type passes, and for defining the position of the sliding side of the table carrying the upright side of the tube and first cutter. 6, They have also facilitated the setting of the machine by making the cutters used for planing the rubbed sides adjustable in a horizontal and in a vertical plane, so as to ensure a flat cut upon the type. 7, In some modifications the type may be stationary, and the cutters moveable while the adjustment is effected, and the type held square by similar types in line on each side of it, instead of by grippers as in the before-mentioned invention. *Patent completed.*

2515. J. Bower. *Improvements in railway sleepers.* Dated September 12, 1862.

This relates to certain new forms and descriptions of cross sleepers for use on railways and tramways, which the inventor proposes to make of wrought or cast iron, or other suitable metal, of any length, and to be in cross section (trough like) and of a rectangular, triangular, curved, or angled V form, or of a section compounded of two or more of these forms. These sleepers are further provided with flat flanges or bearing surfaces projecting at the top edges, and drilled or bored for rivets or screw bolts, by which passing through these holes and through corresponding holes in the range flange the sleeper and rail are securely fixed to each other. In the case of the "double-headed rail," the flanges of the sleeper are fixed by like means to chairs carrying the rails, and bearing on both flanges of the sleepers. The convex or lower external part of the sleeper is intended to rest on the ballast in the usual way. The upper surface of the sleeper or its flanges may be recessed or grooved for the reception of the rail, or chair carrying the rail, to secure the gauge of the line; or the sleeper may be manufactured and used without such recesses. *Patent abandoned.*

2516. J. Rowell. *Improvements in pillars and apparatus for straining wire.* Dated September 12, 1862.

The details of this invention are too voluminous to be quoted here. *Patent completed.*

2517. J. Howie. *Improvements in the construction of the crossings and switches of railways.* Dated September 12, 1862.

Under one modification or system of arrangement embodied in this invention, in place of laying down rails of the ordinary kind 14 or 15 ft. in length, short lengths of rail are inserted in the main and siding rails at the parts which are found to wear away most rapidly by the traffic of the carriages. The parts which are found to give way so much sooner than the other portions of the line are those which are contiguous to the tongue or point rails; at these parts a comparatively short length of rail is interposed in the line of the ordinary rails, and forming a continuation of the same. These short lengths of rails are, by preference, formed of steel or case-hardened iron, in order that they may wear as long, or nearly as long, as the rails which are subjected to the ordinary wear and tear of the line. These short lengths of rail are fastened by means of fish-plates extending for some distance beyond the abutting ends of the rails, and are firmly bolted together. A portion of the bolts may be passed through both the rails, so as to obtain a very firm junction, and prevent all rocking or lateral motion of the rails; the fastening of the parts may, however, be effected in various other ways. In conjunction with these short lengths of hard metal rails it is proposed to make the extremities of the tongue rails, extending backwards a length of 4 or 5 ft., by preference, of steel or of case-hardened iron, so that these parts may wear in unison with the contiguous hard metal rails. *Patent abandoned.*

2518. A. J. Moreau. *An improved mode of or process for reducing or melting pulverized metals or metallic ores.* Dated September 12, 1862.

The iron sand or pulverized metal to be operated upon may be operated upon alone, or mixed in various proportions with metallic filings or turnings, so as to render the metal softer. These filings and turnings have the advantage of being homogeneous and of melting with the iron sand at the same temperature and in the same time as they are intimately mixed in the same block. In order to effect this reduction, the patentee first mixes the metal when in a finely divided state with a quantity of turnings and filings, the proportions of which may vary according to the degree of softness of metal it may be desired to produce. This mixture of the iron sand with filings or turnings having been effected, he incorporates these matters with some combustible matter in a plastic state, so as to dispense with the use of any other fuel. For this purpose he prefers peat, the heat of which is the most intense and the most regular; this substance also produces during the process a very dry gas in great abundance—that is to say, a hydrogen gas of very great calorific power. If peat is not to be obtained with facility, he takes small coal, or pulverized charcoal, or coke, and incorporates all these matters with a suitable proportion of peat in a damp state, and he forms the whole into a homogeneous and compact mass, which should be triturated and moulded into bricks or cakes of any convenient form and size, and which, on being exposed to the air or dried in ovens, will become as hard as stone. The bricks or cakes thus composed of ore, or metal, and fuel, when dried are ready to be operated upon, for which purpose they are to be thrown into the mouth of the furnace, and by reason of their form spaces will be left between them, thus leaving free passage upwards for the flame from the fuel and gases below. *Patent completed.*

2519. H. Higgins. *Improvements in machinery or apparatus for opening, cleansing, or carding cotton, and other fibrous materials.* Dated September 12, 1862.

The object of the first part of this invention is to work and clean the fibrous material by means of a series of card rollers, and to remove it at the end of such series in a loose form by means of a brush or other suitable agent, so as to collect it upon a cage and form a lap. The invention also consists in using a series of rollers, as aforesaid, in combination with beaters which act upon the material as in the usual scutcher. Another part of the invention relates to the machine usually termed the carding engine, and consists in the application of two or more "lickers-in" placed one before the other, revolving in the same direction, and acting as mutual workers, and in combination also with a roller or rollers situated between them. Another part of the invention relates to carding rollers or cylinders, and consists in the application of a collar or equivalent part of such a diameter as to prevent the rollers or cylinders to be set too near to each other. *Patent completed.*

2520. G. Bedson. *Improvements in rolling wire and other rods or bars of metal.* Dated September 12, 1862.

This invention consists in applying rolls to a furnace in such manner that they may draw the heated metal from it or through it, so that the operations of heating and rolling are performed simultaneously. *Patent completed.*

2521. W. Harkes. *Improvements in machinery for mowing and reaping.* Dated September 13, 1862.

This invention consists—1, In placing the cutters in a line with the axis of the driving wheel, instead of placing them either before or behind, as now customary; this position allows the cutters to follow the inequalities of the ground. 2, In connecting the shafts for the horse and the seat for the driver to a swivel frame connected to a centre stud in the main frame of the machine, for enabling the machine to be worked alternately to and fro across the field. 3, In making the cutters with knife edges at each edge of the blade, and in making the guides through which the cutters work to project on both sides of the blade; also in making the outside guide piece to swivel on a centre to provide for the alternate to and fro working of the machine. 4, In supporting the cutters in a frame, which frame is acted upon when required by a treadle and lever from both ends of the machine, to enable the driver to raise or lower the cutters at pleasure. *Patent abandoned.*

2522. H. J. Lewis. *Improvements in engines to be worked by means of water.* Dated September 13, 1862.

This invention relates to an arrangement of engine whereby the pressure of water from ordinary water works, or any other head of water, is made available to produce reciprocating motion in a piston, which motion is converted into continuous rotary motion by means of a connecting rod and crank, as in the ordinary steam engine. *Patent completed.*

2523. M. Chadwick. *Improvements in machinery for doubling, folding, or plaiting cloth or other woven fabrics.* Dated September 13, 1862.

This invention consists—1, in the application of moveable cross rails or wedges, instead of cards in the old plaiting machine. The rails or wedges in the action of the knife and cloth raise, and at each return of the knife the rail falls and presses against the cloth in the form of a wedge, and so secures the material. 2, The inventor gives the oscillating motion to the knife by means of an eccentric placed on the crank; this eccentric is fixed to a rod connected to a lever, which is placed on the knife shaft; in the action of the crank the eccentric will give a to and fro motion to the rod and lever, and thus give the required oscillating motion to the knife. *Patent abandoned.*

2524. W. J. Williams. *Improved apparatus or machinery for punching, cutting, or pressing metal or other plates or substances, which said improvements are also applicable to tension rods.* Dated September 13, 1862.

This invention consists in forming or constructing a machine for punching or piercing metal or other substances by manual power, that is to say—1, the patentee forms the frame of the machine of weight and thickness adapted to the purpose for which it is to be employed. On one end of this frame is the ordinary die or punching bolster to receive the punch tool or die, and above this, at a suitable distance, is a hollow neck shank or boss, having a thread cut in it; within this works a hollow spindle or shaft, with an external and similar thread cut in its extremity. This shaft is actuated by a lever of any convenient length, and is prolonged so as to allow of it being screwed to the bottom of the boss, shank, or neck before mentioned. Within this spindle or shaft is another spindle or shaft, also with a thread cut upon its exterior, and working in a corresponding thread in the inside of the first-mentioned one, and extending through the boss, one extremity carrying the punch, and the other end being carried up through the hollow spindle which serves as a guide for it. The thread on this last-mentioned spindle is formed with a slight difference in the pitch, though the course of the thread runs in the same direction. Thus, when the spindle or shaft first-mentioned has arrived at the bottom of the screwed boss, say a distance of several inches, this inner spindle will be advanced a very small distance; in practice, this distance would be about a quarter of an inch. By this means, he gains an enormous power, and can easily punch any-sized holes in ordinary boiler and other plates by very little exertion, though the action is necessarily very slow. Having broken the hole almost through, he turns the handle connected with the inner screwed spindle or shaft, which forces the punch or tool through the metal, cutting a clean and distinct hole. *Patent abandoned.*

2525. T. W. Cowan. *Improvements in the construction of portable or fixed pumps.* Dated September 13, 1862.

This invention relates to an improved method of constructing force and other pumps by means of the introduction of four pistons or valves with a double-barrelled pump. The apparatus consists of two barrels parallel to each other, each barrel having a double-action within itself. On the piston or valve rod in one barrel the valve acts so as to draw the water or other liquid. The leather or other material forming the valve is placed on the upper side of the piston, the other and lower piston in the same barrel having its valve or flap on the under side. The arrangement is reversed in the other barrel, the upper piston having the valve on its under side, and the lower one having the valve on its upper face. By this arrangement two pistons will be sucking or drawing in the water or other liquid, and the other two forcing it out. On one of the valve rods is placed an air vessel which moves with the valve rod and within the barrel. *Patent completed.*

2526. A. V. Newton. *An improved mode of and apparatus for sleeking, creasing, and raising leather.* (A communication.) Dated September 13, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2527. H. Bennett. *Improvements in machinery or apparatus for the rolling of wire rods.* Dated September 13, 1862.

This invention consists in arranging a pipe or conductor of cast or wrought iron or other metal (or when necessary a series of pipes or conductors), so that upon the iron or other metal being entered in one groove or hole of the rolls, the said pipe or conductor will act so as to conduct the wire into another groove or hole, and so on by using several conductors from one groove or hole to another until the piece or rod of iron or metal to be rolled is in several grooves or holes at once. As the iron or other metal comes from between the rolls rather flat, it has to be placed in the next groove or hole edgewise; therefore the patentee constructs the said pipe or conductor so that, although the iron or metal may enter flatways, it may come out edgeways at the other end, and be conducted in its proper form into the next hole or groove. These pipes or conductors may be fastened to a moveable carriage or traversing arrangement, so that the pipes or conductors may be drawn back when required to prevent the iron or metal accumulating between the delivery-hole or groove and that receiving it. By this invention each hank or rod of iron or metal may be rolled much longer than at present without deteriorating its quality. *Patent completed.*

2528. W. Palmer. *Improvements in lamps and in apparatus used therewith.* Dated September 23, 1862.

These improvements are applicable in constructing lamps wherein the burning fluid is forced up to the wick, and wherein the excess of fluid thus raised is allowed to flow away from the wick through openings near the upper part of the outer wick tubes. In these descriptions of lamps it has been found that, when hydro-carbons are used as burning fluid, they are liable to be driven out in conjunction with streams of atmospheric air to become ignited. Now these improvements in such description of lamps consist in applying to such holes and passages finely woven wire, or other fabric or material, so as to cause the fluid and air to be as it were filtered or prevented spurting out in a manner to become ignited. In order to fill such lamps, a valve is used, on the upper part of which is formed a neck with a hole or opening between it and the vessel, so that the fluid may flow into the neck when the vessel is tilted; and at or near the lower part of the neck is an outlet with a rising spout in order to admit of the fluid being poured from the lower part of the neck into the lamp; a valve is used to close the hole or passage between the vessel and the neck, and this valve is carried by a cylinder having a screw thread around it, which fits a corresponding female screw on the interior or the neck, so that by turning the inner cylinder the valve is moved away from its seat. *Patent abandoned.*

2529. E. G. Chant. *Improvements in self-binding portfolios or holders for newspapers, music, documents, letters, and other papers, or for woven or other fabrics or articles* *which it may be desired to bind or hold together.* Dated September 15, 1862.

This invention has reference to clipping and securing the papers and other articles by the aid of the back or folding or hinged portion of the portfolio or holder, and consists in effecting the clipping and securing by means of cords, strings, or equivalents, or strings passing from one leaf or side of the portfolio or holder to the other leaf or side, and by loops, eyes, or guides for the cords or strings on and at or near the back of one or both of the leaves or holders, and by spring compensations on and at or near the back of one or both of the leaves or holders, to compensate for the varying thickness or quantity of the articles to be bound or held together, as the same may be severally added from time to time. *Patent completed.*

2530. W. G. Rawbone. *Improvements in gun barrels, &c.* Dated September 15, 1862.

These improvements in gun barrels consists—1, in making a night and day line on the barrels, that is, a line upon the middle of the top of the barrel, or upon the top of the rib of the barrel, the line being bright while the other parts are dark. The reflection of the light upon the bright line assists in obtaining an accurate aim. The improvements in gun barrels consists, 2, in making a longitudinal undercut dovetail groove in the flat rib of the said barrels, in which dovetail groove the traversing sight of the firearm is made to slide, instead of making the said sight work in grooves cutting the edges of the said rib. *Patent completed.*

2531. J. Pender. *Improvements in hoops for fastening bales.* Dated September 15, 1862.

This consists in making hoops with one or more elongated holes at one end, and one or more circular holes at the other end, for containing rivets, studs, or buttons. One part of each elongated hole is sufficiently large to allow the head of the rivet, stud, or button to pass through, and the other, or narrow part, is of such a size as to allow the neck or shank to pass, but not the head. For punching the holes in the band of hoop iron, the patentee uses a punching and cutting machine with punches and dies of the size and shape of the holes to be punched, and curved or straight cutters for cutting the ends of the hoops, so that the machine will cut each hoop at one or both ends at the same time as the holes are punched. *Patent completed.*

2532. E. Balurforth. *Improvements in machinery employed in finishing textile fabrics, commonly called "raising gigs."* Dated September 15, 1862.

This invention consists in the application to raising gigs of a cylindrical brush placed in contact with the teasels on the swift, to which rotary motion is given at a greater surface speed than the surface speed of the said swift, and in the direction of rotation thereof, by which means the flocks and dirt are constantly removed and prevented from accumulating on the teasels during the time the machine is in operation, thus avoiding the frequent stoppage of the machine for the purpose of cleansing the teasels, as heretofore. *Patent completed.*

2533. W. L. Tizard. *Improvements in the construction of ships, vessels, cupolas, and forts, and in apparatus employed therein.* Dated September 15, 1862.

This invention was described and illustrated at page 26 (No. 200), of this journal. *Patent completed.*

2534. H. M. Radloff. *An improvement in vessels for filtering oils.* Dated September 15, 1862.

Hitherto oils have been filtered in vessels with plain sides, in which a filtering body has been compressed and held between two perforated plates, the oil being filtered by ascension. From the sides having been plain, instead of the whole of the oil passing up through the filtering body, a portion has found its way between the filtering body and the plain sides of the vessels. Now this invention consists in forming the filtering vessels in two parts, the upper part carrying a flange fitting inside the other part, and resting upon the edge of the upper perforated plate. The patentee also forms a ledge inside the under part, upon which the upper perforated plate rests. No portion of the oil can pass except through the filtering body. *Patent completed.*

2535. J. Webster. *Improvements in the manufacture of nitric and nitrous acids, and other nitrogenous compounds.* Dated September 15, 1862.

In carrying out this invention, the patentee first generates the binoxide of nitrogen gas from nitrous acid, or any other body containing the binoxide of nitrogen gas. If using nitrous acid, he causes the acid to be run into a suitable retort or vessel red hot, and filled with pumice stone, or other similar material that will stand a red heat without being decomposed by the acid. The nitrous acid being run or dropped upon the red hot pumice stone becomes converted into binoxide or dentoxide of nitrogen gas NO^2. This gas is then conveyed to a vessel or generator, or condenser, furnished at a suitable position at the side and near the bottom with a draught hole or regulating damper, and at the top with an outlet into a chimney to obtain a draught; or the draught may be insured by other means if required. One or more of these generators or condensers may be employed according to circumstances. The binoxide of nitrogen gas NO^2 may be conveyed to the generator from the retort by a pipe having its ingress to the generator at or near the bottom of that vessel, and opposite the draught pipe, to meet the current of air passing through the draught pipe. The binoxide of nitrogen gas NO^2, coming into contact with the air, instantly absorbs two of oxygen from the atmosphere, and becomes nitrous gas NO^4. The generator contains a number of trays or divisions upon which are laid the following materials (varying according to circumstances): thus, if he requires to make nitric acid and nitrous acid, the materials upon the trays will be gravel, sand, broken pumice stone, or other similar substances, upon which the acid will not act damped with water. If he requires to make any particular nitrate, he places upon the trays, instead of the substances before-named, the caustic base of such nitrate damped with water; thus, if he wishes to make the nitrate of potass, he employs the caustic of potass; if the nitrate of soda, the caustic of soda; and so on; only in the case of using caustic of soda, care must be taken that it be mixed with gravel or sand to prevent its offering by its density any obstruction to the passage of the gas, and to afford a larger surface for the action of the gas. Carbonates, either alone or mixed with the caustics, may also be employed if preferred. *Patent completed.*

2536. E. Astel. *Improvements in urinary utensils, also applicable to fixed and portable commodes.* Dated September 16, 1862.

This invention is not described apart from the drawings. *Patent completed.*

PROVISIONAL PROTECTIONS.

Dated Feb. 20, 1863.

468. W. Clark, 53, Chancery-lane, engineer. Improvements in projectiles for ordnance. (A communication.)

Dated Feb. 27, 1863.

551. H. Fehr, merchant and distiller, 63, Fenchurch-street. Improvements in the treatment of mineral oils.

Dated March 5, 1863.

629. J. Elsey, Nottingham, lace manufacturer. Improved apparatus for the winding of lace on to the work roller in warp lace, bobbin net, or twist lace machines.

Dated March 9, 1863.

645. H. Whittles, Milnrow, Lancaster, engineer. Improvements in machinery or apparatus for collecting the condensed steam or waste water from places where steam is used, and returning the same to the boiler.

647. J. Cowley, Oxford, engineer. Improvements in machinery or apparatus for manufacturing bricks, tiles, pipes, and mouldings.

649. J. Isherwood, Sharples, near Bolton, yarn bleacher. Improvements in working presses for making up yarn in bundles.

651. C. H. Lea, Shallowford, near Stone, Stafford, miller. Improved apparatus for opening and closing the gates of railway crossings, which apparatus also acts simultaneously upon the signals.

653. P. Hugon, 56, Rue de l'Ouest, Paris, civil engineer. Improved machinery for obtaining and applying motive power.

657. W. E. Newton, 66, Chancery-lane, civil engineer. Improvements in the construction or laying of wooden floors. (A communication.)

Dated March 11, 1863.

661. F. Cooke, Denton, Lancaster, hat manufacturer. Certain improvements in the manufacture of hats or coverings for the head.

663. J. Cassell, La Belle Sauvage-yard, publisher. Improvements in moderator lamps to adapt them to the burning of petroleum and other mineral oils and hydro-carbons. (A communication.)

665. W. R. Mulley, Plymouth, surveyor to Lloyd's Register. Improvements in sheathing iron ships, caissons, and other like structures.

671. J. Tomlinson, Roach Iron Works, Rochdale, machinist. Improvements in machinery for opening twisted yarns and woven fabrics.

673. W. Rossetter, Accrington, mechanic. Improvements in back beam warping machines.

Dated March 12, 1863.

675. H. D. and J. W. Taylor, Huddersfield. Improvements in finishing woollen, worsted, and other fabrics, and in machinery or apparatus to be used therein.

676. L. Dessens, 45, Boulevart Bonne Nouvelle, Paris, gentleman. An improved bath, or bathing machine, adapted for deep water.

677. W. Clark, 53, Chancery-lane, engineer. Improvements in breech-loading firearms. (A communication.)

679. J. Polkinghorne, Redruth, Cornwall, tin smelter. Improvements in treating tin ores, and in apparatus for treating ores and matters containing arsenic.

Dated March 13, 1862.

681. J. Harris, Pontypool, Monmouth, iron plate roller, J. Butler, Pontypool, iron manufacturer, and J. H. Fraser, Llanvrechva Upper, Monmouth, manufacturer. Improvements in machinery for rolling armour plates, bridge plates, boat plates, and other plates and bars of iron.

683. J. Taylor, Burnley, cotton spinner. Improvements in fire bars and bearers.

685. W. H. Stübbe, New York. Improvements in governors for marine and other engines.

687. J. H. Johnson, 47, Lincoln's-inn-fields, gentleman. Improvements in fastenings suitable for portions of harness and other purposes. (A communication.)

Dated March 14, 1863.

689. W. E. Gedge, 11, Wellington-street, Strand. An improved plough. (A communication.)

691. W. West, Treadenham House, St. Blazey, Cornwall, civil engineer. Improvements in valves.

693. J. W. McCarter, The Foyle-street Sawmills, Londonderry. Improvements in machinery for sawing or cutting wood.

699. J. Walworth, Bradford, corn mill machine maker. Improvements in machinery or apparatus for washing or cleansing and drying Egyptian wheat, beans, and other kinds of grain or seeds.

Dated March 16, 1863.

701. E. Oliver, engineer, and G. Myers, draughtsman, Rotherham. Improvements in apparatus for lowering and disengaging boats from vessels.

702. F. Hoyos, 42, Rue de Chaillot, Paris, manufacturer. An improved stove or fire-grate for heating, cooking, boiling, or other similar purposes.

703. T. W. Willett, 31, Charing-cross, captain. Improvements in means for reefing and furling square sails of ships and vessels from the decks thereof.

705. G. P. Beley, Liverpool, merchant. Improvements in discharging projectiles below the water line of navigable vessels and other structures.

709. W. G. Eavestaff, Great Russell-street, pianoforte manufacturer. Improvements in the construction of pianofortes.

Dated March 17, 1863.

713. W. E. Gedge, 11, Wellington-street, Strand. Improvements in the modes or means for framing pictures, looking glasses, and other objects. (A communication.)

714. W. H. Emett, 8, St. George's-terrace, South Kensington, lithographer. Improvements in processes for facilitating and combining the art of writing with engraving together on stone, applicable to maps, plans, specifications, and other lithography, which improvements are also available for retransfers to zinc or stone, or printing from original.

717. G. De Laire, Imperial Mint, Paris, chemist. Improvements in the manufacture of brown colouring matters. (Partly a communication.)

719. W. Symington, Market Harborough. Improvements in the process of, and apparatus used in, roasting and treating coffee and other organic substances.

720. W. C. Wild and J. H. Randel, Birmingham, dealers in precious stones. A new and improved mode of inlaying gold and other metals in glass, and in a composition suitable for the manufacture of jewellery and other ornaments, buttons, and other similar articles.

721. W. Donbavand, Manchester, scale beam and weighing machine manufacturer, and D. Critchton, machinist. Improvements in looms for weaving.

722. J. Roberts, Manchester, organ builder, and R. Naylor, gentleman. Improvements in organs, harmoniums, and pianofortes.

723. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in the manufacture of spoons and forks. (A communication.)

725. W. E. Taylor, Enfield, near Accrington, Lancaster, cotton spinner and manufacturer. Certain improvements in machinery for reeling, winding, warping, and beaming yarn.

729. T. Oldknow, Ashforth's Factory, Nottingham, general machinist. Improvements in the construction of jacquards employed in bobbin net or twist lace machines.

732. A. Morel, Rue du Marché, Brussels, engineer. Improvements in apparatus for generating carbonic acid.

733. J. D. and A. P. Welch, Gutter-lane, straw hat manufacturers. Improvements in bleaching, and in reducing and brightening the colour or tone of dyed straw plaits and straw.

Dated March 19, 1863.

735. E. Lever, Manchester, manufacturer of colliery brattice cloth and flexible tubing. An improved composition for the coating and preservation of canvas and other materials to make them waterproof and non-inflammable.

741. G. H. Smith, Ipswich, machinist. Improvements in sewing machines.

Dated March 20, 1863.

744. A. Barclay and A. Morton, engineers, Kilmarnock. Improvements in certain apparatus for injecting and ejecting fluids.

745. J. Nield, iron founder, and T. A. Nield, engineer, Dukinfield. Improvements in core barrels.

746. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in machinery for beating and drying wool and other textile and filamentous substances. (A communication.)

748. G. Wilson, Cyclops Steel and Iron Works, Sheffield, engineer. An improvement in the manufacture of springs.

749. G. Coles, Gresham-street West, merchant, J. A. Jaques, chemist, and J. A. Fanshawe, engineer, Tottenham. Improvements in machines or apparatus for washing or wringing clothes or fabrics.

750. C. Pryse, Birmingham, manufacturer, and D. Kirkwood, gun maker. Improvements in breech-loading firearms, part of which improvements are also applicable to other descriptions of firearms.

752. F. De Wyldé, Trinity-square, Tower-hill. Improvements in the manufacture of cement from gypsum.

Dated March 21, 1863.

754. F. and A. Roberts, 5, Victoria-cottages, Barton-terrace, Gloucester. Improvements in agricultural implements, and in apparatus for working the same.

755. C. De Groote, Brussels, shorthand writer. Improvements in the construction of lamps with circular burners, or wicks for the combustion of petroleum, schist, and other volatile oils, parts of said improvements being applicable to gas burners, night lights, and lamps burning spirits and animal oils.

760. F. Applegate, Bradford-on-Avon, woollen manufacturer. Improvements in time indicators.

Dated March 23, 1863.

764. W. Johnston, Glasgow, metal merchant. Improvements in apparatus for lighting and heating.

766. J. Eyles, George-street, Portman-square, milliner and dress maker. Improvements in cheffonier bedsteads.

Dated March 24, 1863.

770. G. Davies, 1, Serle-street, Lincoln's-inn. Improvements in wrappers or papers for needles, and in machinery or apparatus for sticking needles therein. (A communication.)

772. H. Williams, Portmadoc, Carnarvon, engineer. Improvements in machinery or apparatus for dressing slates.

774. J. Kirkham, Euston-road, civil engineer. Improvements in the manufacture of iron and steel.

Dated March 25, 1863.

776. J. White, Finchley, surgeon. Improvements in protecting the surface of the iron and steel of ships and all other structures, except that of cables, tanks, and boilers, while in contact with water, from decay; in preventing or abating, and in facilitating the removal of foulness of ships' bottoms; and in giving a capacity of increased speed to ships.

778. J. Leach, cotton spinner, and J. Anderson, manager, Ashton-under-Lyne. Certain improvements in machinery or apparatus for preparing and spinning cotton and other fibrous substances.

780. **G. Stuart, Glasgow, commission merchant.** Improvements in bleaching jute fibre.

782. **R. Armitage, Huddersfield, and C. Senior, Dead Waters, near Huddersfield, engineers.** Improvements in means or apparatus for stretching fabrics.

784. **T. W. Gore, New Whittington, Derby, builder.** An improved method of uniting earthenware, metal, and other pipes.

Dated March 26, 1863.

788. **R. Mushet, Coleford, metallurgist.** An improvement or improvements in treating steel and iron prepared by the pneumatic process.

792. **W. Johnson, Warwick-square, manufacturer.** Improvements in pocket books, purses, wallets, and bill cases.

794. **W. Tod and R. Paterson, Glasgow, engineers.** Improvements in portable apparatus for working drills, and other instruments.

796. **J. H. Johnson, 47, Lincoln's-inn-fields, gentleman.** Improvements in furnaces or fire-places, and in apparatus to be used in connection therewith. (A communication.)

798. **W. Blake, Glasgow, manufacturing stationer.** Improvements in the manufacture of labels for luggage and other articles.

800. **E. Easton, The Grove, Southwark, engineer.** An improved application of hydraulic apparatus for lowering full casks and other goods, and raising empty casks or vessels.

PATENT APPLIED FOR WITH COMPLETE SPECIFICATION.

Dated March 25, 1863.

786. **G. T. Key, Lieutenant, Portsmouth.** Improvements in fog and other signals.

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

From the *London Gazette*, March 31, 1863.

2806. **W. S. Kennedy.** Apparatus for applying fomentations and other external remedies to the throat.

3167. **T. M. Elton.** Manufacture of soap.

3170. J. Steinthal. Moulder's blacking.

3171. F. Palling. Fountain penholder.

3173. W. Austin. Cartridge cases.

3176. J. Halford. Preparation and treatment of small coal or slack, whereby a certain carbonaceous product is obtained and rendered available for use in the manufacture of iron and steel in the processes of casting and moulding metals, and in the manufacture of paint and such like articles.

3178. F. W. Hartley. Obtaining certain products resulting from the manufacture and purification of coal gas. (A communication.)

3181. D. and D. Auld, jun. Working furnaces and steam-boilers.

3182. J. L. Linton. Means of generating steam. (A communication.)

3183. D. Veerkamp and C. F. A. Van Trigt. Treatment of old manufactured fabrics.

3189. J. H. Johnson. Apparatus for indicating the pressure of electric conductors in foreign bodies. (A communication.)

3192. S. J. Browning. Machines to be employed in brewing.

3200. F. G. Taylor. Washing machines.

3207. Rev. H. Moule. Locomotive engines.

3211. M. Henry. Manufacture of leather. (A communication.)

3214. G. F. Griffin. Permanent way of railways.

3216. J. Irwin. Machine for cultivating land.

3217. R. Fiude. Looms.

3221. P. W. Reuter. New compound to be used for dyeing and printing purposes. (A communication.)

3230. G. F. Blumberg. Method of, and apparatus for, producing designs in or on glass.

3235. D. Graham. Steering and manœuvring ships or vessels.

3258. R. Wallis. Apparatus for loading and unloading vessels.

3262. L. Christoph, W. Hawksworth, and G. P. Harding. Drilling, drawing, and rolling metals.

3283. R. A. Brooman. Kneading machines. (A communication.)

3294. J. H. Johnson. Steam generat s. (A communication.)

3315. W. Clark. Umbrellas. (A communication.)

3359. W. and A. Smedley. Manufacture of textile or looped fabrics on warp lace machines.

3397. W. S. Longridge. Machinery for rolling tyres, hoops, and rings.

3400. A. V. Newton. Machinery for attaching metal eyelets to cloth and other materials. (A communication.)

3453. C. F. Varley. Electric telegraphs.

307. W. G. Valentin and F. Levick. Generating combustible gases.

349. J. James. Covering for hooped skirts.

529. W. E. Newton. Stereotype plates for printing purposes. (A communication.)

532. J. Inglis. Apparatus for folding paper and other fabrics or materials.

569. D. Collinge. Apparatus for cleaning, steaming, and preparing cotton or other fibrous materials to be spun.

587. G. Haseltine. Sewing machines. (A communication.)

594. G. Price and W. Dawes. Burglar-proof safes and strong-room doors and frames.

658. J. H. Johnson. Treatment of certain fibrous vegetable substances with a view to the production of textile materials therefrom. (A communication.)

661. F. Cooke. Manufacture of hats or coverings for the head.

680. H. B. Barlow. Looms for weaving. (A communication.)

736. H. Wilde. Construction of steam boilers.

738. J. Saunders and J. Piper. Apparatus employed in the manufacture of tin and terne plates.

754. F. and A. Roberts. Agricultural implements.

778. J. Leach and J. Anderson. Preparing and spinning cotton and other fibrous substances.

780. G. Stuart. Bleaching jute fibres.

786. G. T. Key. Fog and other signals.

The full titles of the patents in the above list can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners' office particulars in writing of the objection to the application.

LIST OF SEALED PATENTS.

Sealed April 6, 1863.

2698. J. Newnam.
2699. T. Beards.
2708. A. Forbes.
2710. H. D. P. Cunningham.
2711. J. K. Hampshire.
2712. J. and M. A. Beale.
2714. C. F. Terry.
2728. A. V. Newton.
2731. L. Hosch.
2733. R. E. Green and J. Cockcroft.
2738. D. S. Sutherland.
2739. E. Weallens.
2741. J. J. Shedlock.
2743. A. Vennedy.
2744. R. A. Brooman.
2746. J. Durrant.
2748. A. V. Newton.
2758. J. Gumbley.
2760. E. B. Wilson.
2765. E. Barlow, J. Clough, and F. Hamilton.
2781. C. de Bergue.
2784. J. B. G. M. F. Piret.
2790. W. Barningham.
2808. J. H. Johnson.
2812. J. Bentley.
2317. W. Clark.
2855. W. Clark.
2877. W. Clark.
2894. A. Peek.
2940. W. E. Newton.
2950. F. E. Sickels.
2952. W. Jenkins.
3046. C. Socin.
3166. W. Longley.
3275. A. V. Newton.
3234. G. T. Bousfield.
3483. F. Applegate.
67. L. Hull.
119. G. T. Bousfield.
155. G. T. Bousfield.
208. E. Straugman.
225. F. Tolhausen.
285. J. Mackenzie.

PATENTS ON WHICH THE STAMP DUTY OF £50 HAS BEEN PAID.

861. T. Ingram.
886. J. Hamer.
891. T. Aveling.
896. E. Heywood.
921. O. Vandenburgh.

PATENTS ON WHICH THE STAMP DUTY OF £100 HAS BEEN PAID.

812. A. Morton.
813. W. Terry.

MECHANICS' MAGAZINE.

LONDON, FRIDAY, APRIL 17, 1863.

MARINE ENGINE IMPROVEMENTS.

Were we asked in what field steam-power offered the greatest rewards, and the most favourable opportunities for improvement, under certain limitations, we should answer without hesitation, on board ship—the situation of all others where reduction of weight, diminution of occupied space, and the utmost economy in the consumption of fuel, are called for. Many may think the subject of steam-engine economy hackneyed; to the theorist, who in his study elaborates theorems, and studies equations, until his eyes dim and his brain reels, the subject may well seem so; he may exclaim, "What more can be said or written on the question? it is exhausted;" but to the practical man the case is far different; to him, the subject must always prove interesting, because without it he cannot think to hold his own in the race now run by engineers, each striving after the prize, that prize a noble one, wealth and honour, and a place high amongst men, to him who can make the best and (shall we say "consequently?") sell the greatest number of engines. We do not mean to say that engineers exert themselves to improve steam machinery solely for money, or even for power. To many the work of improving is in truth a labour of love; and from the labour of such men, when untrammelled by existing circumstances, and possessed of a thorough practical knowledge of the actual requirements which are most conducive to success, we may expect the very happiest results; but, unfortunately, such men can rarely give scope to their inclinations. The moment the engineer sets foot on board ship he finds himself trammelled on every side; and to this cause, far more than to want of skill, knowledge, or inclination on his part, we attribute the admittedly very slow progress which steam-engine economy makes, not only in the Navy, but in the merchant service.

Most of our great engineering establishments are old ones, dating their origin far back, to those old days when steam was in its infancy; they have arrived at their present standing, not by a spontaneous growth, but by the unwearied exertions of able men—men whose dearly-bought experience is not to be overthrown by any array of calculations however tempting, and who refuse to listen to the voice of the mathematical charmer, "charm he never so wisely." How many obstacles have been overcome, how many disheartening failures contended with, what enormous sums of money spent, in gathering up that store of knowledge which has led to that success which constitutes the pride of our Maudslays and our Russells, our Penns and Watts—men to whom England is as much indebted for her naval supremacy as to Howe or Nelson! From such men we have received steam vessels second to none in the world, with engines which, although heavy and costly, and almost free from even a pretence to economy, are perfectly trustworthy, and justly esteemed in consequence. It is scarcely likely that such men will take the initiative in any further attempt at marine engine improvement; they more likely will rest, content with their well-earned laurels, and gazing serenely from the elevation which they have reached, say to younger firms, "Go thou and do likewise;" and to those engineers who have wealth and honour yet to obtain, we say that nowhere will they find opportunities for the attainment of both equal to those afforded by successful marine engine construction.

Coals at home at home are cheap; a few tons more or less per day are of little importance to wealthy companies; but how stands the matter when we get to foreign stations, where coals become black diamonds indeed, and the saving of fuel a matter of the most paramount importance? In such situations, we believe, few would not be content to sacrifice space in the ship, and even submit to an increase of weight in the engine, in order to keep down the consumption of fuel; how much more gladly then should we avail ourselves of such improvements as not only reduce the consumption of fuel, but also weight and space! That such improvements are within our grasp, are ready for our adoption, is certain; why then do we not avail ourselves of them to a greater extent than we do? For the same reason that the shepherd king refused to go in armour to contend with the Philistine, because "he had not proved it."

We have already said that the moment the engineer sets his foot on board ship, he finds himself trammelled on every side by considerations of available space, weight, first cost, power, &c.—nay, even when the engine-room is handed over to him by the shipbuilder, he cannot consider himself at liberty to use that space, limited as it is, as he pleases; considerations of "trim," as influencing the future seagoing qualities of the ship, must enter into all his dispositions and calculations; and thus, perfect as any general design may appear on paper, we commonly find such alterations necessary, to meet the different requirements of individual cases, that little more than the general principles which have guided the designer remain; all matters of detail become merged in the one consideration, "expediency." Thus we find that marine engines as a class make less progress in economics than any other; let us enter a little deeper into "the reason why," a question often asked, seldom satisfactorily answered.

Scarcely any class of engine has undergone the same amount of improvement as the locomotive; comparatively an infant in years, it shows all the science, culture, and physical development of the full-grown man. All the resources of science and the refinements of art have been lavished on it; always an attractive subject to mechanical minds, from its extreme beauty, its exquisite simplicity, and its vast concentration of power within the smallest limits, it has, perhaps, during the few years which have elapsed since the "Rocket" first astonished those who gazed on its till then unparalleled performance, received more attention than almost any other form of engine; its powers of bringing itself before the public have been unrivalled, and, therefore, it has met with world-wide attention. Elaborate treatises have been written on the minutest points connected with its *physique;* its anatomy studied with a skill worthy of a Hunter, or a Cooper, and as a result we have—the modern locomotive, a machine before which admiration becomes dumb, and even praise sinks into silence.

The great cause of this improvement has been the free scope hitherto allowed, to both the builder and designer, for the free exercise of their respective talents; certain restrictions and limitations, so trifling as scarcely to merit the name, complied with, they may follow the full bent of their inclinations and introduce such alterations as their experience may suggest as likely to prove not only alterations, but improvements.

In many cases we find, too, that, from the skill and attention of locomotive superintendents, particular classes of locomotives have derived certain peculiar advantages, which cause them to stand high in the opinions of the engineering public. Gifted, in most cases, with considerable attainments, and carefully trained in the practical routine of their professions, all such men required were the means and permission to carry out such experiments, and make such alterations as they considered would effect improvements. Directors willingly granted the permission, shareholders eagerly produced the pecuniary requirements necessary, and, as a consequence, locomotives of the most varied construction were turned out from the workshops all over the kingdom. Experiments could easily be entered into; no difficulty could possibly be experienced in trying a new engine, even although it was like nothing which had gone before, and involved the newest and strangest features; for risk was merely nominal, the cost of an engine seldom exceeding £2,000 or £3,000; so that, even if the machine proved an utter failure, and found its place in the scrap-heap instead of working the line, it was a matter of little consequence; no risk of life and limb, considerations far more important, being involved, it was just as safe to travel a hundred miles with such an engine as with one of the ordinary trains; indeed, we find that many of the most valuable results we possess have been obtained from experiments conducted with ordinary passenger trains in the usual course of business.

Ranking before the locomotive in economy, though second to it in importance, we have the Cornish engine—a machine which approaches nearer to theoretical perfection than almost any other which man's ingenuity has enabled him to construct. Here, again, we see the result of genius untrammelled by conditions, either dictated by circumstances, or, worse still, by a lay public. The designer, totally unfettered, devotes all the energies of his well-trained mind to the subject, and regarding the machine in the abstract, instead of the positive, brings it to such perfection that we find a consumption of a couple of pounds of coal per hour gives us a horse-power. How different in all respects is the history of the marine engine from either that of the locomotive or the Cornish; it is a history in which we find little but a constant war between theory and practice—a perpetual struggle, on the part of the engineer, to make that which was right expedient as well. The result has been a class of engines, heavy, bulky, and expensive, both to purchase and use, but possessing the one advantage, which, up to the present, at least, is considered to compensate for the want of every other, they are perfectly trustworthy.

No improvement in the marine engine is likely to meet with universal, or even partial, adoption until it has been thoroughly proved by a series of experiments, conducted on a great scale, by able men; until, in fact, the engine has undergone the same thorough examination as the locomotive, we regret that at present we see little chance of any great undertaking of the kind likely to lead to useful results. It is true that, in a few cases, we see engines embracing many novel features taken into favour, but such cases are too rare to influence the public mind to any considerable extent. Experiments assume a very grave aspect indeed when they are performed on a machine costing tens of thousands of pounds, and on the successful working of which depends, it may be, the lives of hundreds of our fellow-creatures. The breaking down of an engine, the leakage of a boiler, has, ere now, alas, too often carried desolation and misery to many an English home; rash, indeed, would be the man who could for a moment advise such a departure from precedent as would introduce a single element of extra risk on board a steamship; hence we find old plans and models of engine adhered to with a tenacity of gripe which the hand of science has hitherto proved too weak to unloose. Let us ask ourselves, how long can this state of things continue? and, supposing we are dissatisfied with it, to what quarter are we to look for an initiative in a change for the better? These questions are doubtless full of importance, and worthy of the most serious consideration, not only from the engineer, but also from the public at large.

The general practice amongst steam shipping owners is, when giving an order for an engine, to go to some first-class firm celebrated for the construction of the particular class of engine they may require; and this firm would no more depart from the ordinary style of engine on which their reputation rests than they would bore holes in the vessel and send her to the bottom. Indeed, the certainty is that any attempt at the introduction of a decided novelty would be as stoutly resisted by the owners as the actual scuttling of the ship. With all our desire to see science advance, we cannot but admit that such principles are correct in the case of ocean steam-ships. Certain forms of engine a long series of years have proved trustworthy, and the loss of the ship and all hands, or even a considerable delay on her voyage, would be badly compensated for by the saving of a few tons of coals, or the use of a smaller engine. Such steamers are quite unsuited for the first embodiment of a crude idea—crude, because untried. Nor does the Navy offer a much better field. Such ships would badly fulfil their purpose did they break down far from home, perhaps close on an enemy's shore; but, fortunately for the ends of science, all necessary opportunities are still afforded to the engineer by the large class of vessels which carry on our home trade, making short voyages from port to port. Such vessels can rarely encounter any risk comparable with the ocean steamer, and often belonging to companies, who give almost unlimited powers to their manager, who stands, indeed, in nearly the same relation to his employers that the locomotive superintendent does to the board of directors. In such situations, men of talent and enterprise can do much; and, although tied up in many respects, they have nevertheless every reasonable opportunity for experiment; the ships with which they have to deal are generally of moderate size, and making but short voyages little danger is run of a breakdown, which is very unlikely to happen, because the ship spends so much time in port that every opportunity is afforded for the most thorough examination of the machinery.

But, granting that we have thus a sufficiently numerous class of steamers on which to conduct experiments, in what should these experiments consist? We reply, in the first place, that, on board a steamer, an engine on a perfectly new and untried principle should never be made the subject of experiment. We have known such cases where the only result obtained by a really clever thing was loss of money, risk of the ship and crew, and the creation of such a disgust for anything new in the minds of all connected with the ship, as led to the engine's being ignominously removed, and replaced by machinery which could be depended on, although inferior in all other respects to that rejected. All such engines should be carefully tried on shore first, tried for many days in constant work; carefully tried afterwards when on board the ship on the regular trial ground. Many things will be found to require alteration and improvement, and the result will most probably be a vessel which will give perfect satisfaction.

In making use of the word "experiment," we do not mean the conducting of a series of observations in order to obtain certain information which we require relative to the working of any particular class of engine; we mean that every engine the construction of which involves any novelty of principle or working detail, is in its first use an experiment, and requires careful testing ere the lives of passengers, and the property of public companies are suffered to depend on its successful working.

The question only remains, to what quarter should we look for success? The answer is obvious; no further economy can be obtained in steam power without the use of high pressure and expansion. The theorist who proposes such schemes may find fault, and complain of the tardy adoption of his ideas; but he should remember the difficulties which beset the marine engineer in every attempt to make what is theoretically correct practically right also; that the possibility of doing so exists, is proved by the great comparative success which has already attended the labour of many of our junior firms; and we feel little doubt that from such men the subject of steam propulsion will meet with such sound attention as must, in the course of a few years, lead to improvements which will make the marine rank with either the Cornish or locomotive engine in economy. The subject is one full of interest, and we may return to it at another time.

RIB-RIFLED ORDNANCE.

We have received a little *brochure* from an anonymous pen entitled, "Rifling with Ridges in the Gun and Grooves in the Shot."* It is sharp and true to its aim, like a rifled point-blank shot. It comes *àpropos* as a sequel to the article on "Rifled and Smooth-bore Guns" in a recent impression. We do not know the author, but, he is so "to the manner born," we can give a shrewd guess, and so, no doubt, can many of our readers, that he is a well-known eminent artillerist.

"Rifling with ridges in the gun" means that kind of rifling in relief, on the bore of the gun, which we have before referred to as "rib-rifling." It is identical in principle with Mr. Lynall Thomas's plan.

The pamphlet starts with the assertion, "How to send a missile straight or as straight as possible to a direct mark, by the force of gunpowder, is the question to which artillery science cannot yet give a *definitive answer*." The proposition involved in this truism is the problem to be solved by artillerists. The rule for solving it is clearly and correctly laid down by the author—"*the centre of the shot must be brought into the centre of the bore.*" In the smooth-bored gun, he says, the centre of the shot is placed below the centre of the gun "by half the difference of the diameter of the shot and the bore, that is to say, the windage;" and he adds, "there must be windage in a muzzle-loading gun." That is true; but we must not lose sight of the cause which makes that truth a necessity. Without *some windage* it would be difficult, if not impossible, in rapid loading to ram the shot home into a muzzle-loader. This necessity applies to rifled as well as to smooth-bored ordnance, because it arises with reference to firing as well as loading. The great merit of the hexagonal form was claimed by its inventor to be the "mechanical fit," because it was a close fit and prevented windage. But Mr. Whitworth has been obliged to deviate from the close fit. The want of windage was a serious obstacle to loading. It also increased friction in the passage of the projectile out of the twisted rifling, and burst the gun. He now cuts away the angles of the hexagons on the shot, and tapers both ends so that they do not touch the bore. He thus obtains windage, but he abandons his principle.

No system of rifling hitherto invented wholly obviates windage. It is an essential condition of every plan yet tried, and especially of twisted rifling; for, as with the hexagonal, so with every other kind of rifling, the total absence of windage, by the immense strain it causes on the bore in firing, will burst the gun. Even the yielding nature of soft metal casing to the shot is not a guarantee against that disaster, as numerous examples with Armstrong guns testify. It is therefore not correct to state that windage is *per se* the cause of the irregular and uncertain aim of smooth-bored guns. The cause is the position of the shot, not the windage.

The author is more correct when he describes the causes of the deviation of aim with shot fired from a gun, in the words of Sir Howard Douglas and Dr. Hutton. Want of accuracy, according to the former, "arises from the reflections of the ball in passing along the bore, from which a shot acquires a zig-zag motion, and does not generally quit the the cylinder in the direction of its axis;" and the latter, in homely, but energetic terms, says, "The ball is kicked about from side to side; and it depends entirely on the part of the bore the shot last strikes, before it issues out of it, which course it may take."

This source of irregularity in the direction and flight of the shot, is common to rifled and smooth-bored guns; but it is incorrect to ascribe it directly to windage, as cause and effect, because, as we have already seen, the want of mutuality of concentricity in the vertical planes of the bore and the shot, as the latter passes along and out of the gun, is the real cause of uncertainty of aim.

The remedy, as the writer of the pamphlet lucidly explains, is to be found in "bringing the centre of the shot into the centre of the bore;" and this he shows, as it is quite obvious, can be effected by raising the bottom of the shot to a point above the bottom of the cylinder, which shall bring the two centres precisely on the same line, horizontally and vertically. This arrangement, however, which is the true solution of the question propounded in the first sentence we have quoted, is irrespective of windage. The projectile might be supported, or suspended and maintained during its passage out of the gun, in this concentric position, and still have windage space around it which, under that condition, would not disturb the straight direction of the shot. It would only cause a loss of projecting force by the escape of explosive gas.

"The first thing necessary," in the words of the author, "is to make certain that the projectile, while still in the gun, shall move (when propelled) centrally along the bore without striking, and with its centre and axis in and identical with the axis of the bore."

Having described the well-known irregularities of projectiles, he gives his opinion that "this dependence on chance, and all these causes of inaccuracy, will be removed by the expedient of ridges to the gun," that is, by *rib-rifling*. After condemning the "twist groove system as a make-shift, while the art of shooting straight is being invented," he proposes *straight* ridges, and describes the mode of applying them as follow :—"Four ridges in the bore, dividing it longitudinally into equal parts, and the ridges having one and the same elevation, will fix the shot, properly grooved to correspond with the ridges, exactly in the centre and axis of the gun ; and the projectile, if an elongated one, cannot have *any* obliquity of position. The ridges produce the effect of an interior concentric tube of the exact diameter of the shot, and when the discharge takes place the shot cannot possibly deviate from this axial line, and therefore will be delivered, clear of the muzzle, according to the line of aim, and in the true vertical plane of the gun's axis."

---

* Published by T. and W. Boone, 20, New Bond-street, 1863.

All this is quite true. If there be windage, it means that the shot is smaller than the bore of the piece. That being the case, the bottom of the shot resting on the bottom of the bore, will bring the centre of the former below the centre of the latter, unless the shot be lifted the distance of half the difference of the two diameters, and poised in that position. This is precisely what, in the plan we are considering, is proposed to be done by means of the ridges or ribs. We are not, however, prepared to admit that the same effect may not be produced by groove-rifling. We see no reason why ridges on the projectile, and equidistant from its centre, should not fit as accurately to the bottom or edges of grooves, as grooves on the projectile to ridges on the gun. On the author's plan, the weight of the shot will bear mainly on the rib or ribs at the lower part of the bore. At every discharge the shot will slide along the rib, which by constant abrasion will be gradually worn away, and as this process continues the position of the shot will become lower, and its concentricity with the bore will be lost. If the suspension of the shot on side ribs be relied upon, a similar process will take place on the edges of the ribs.

On the other hand, ridges on the shot running in grooves in the bore, may be made to perform the same office of keeping the projectile in a straight course, and concentric to the bore. There would, no doubt, also be a tendency to rub down the bottom grooves in the gun, but it would be much easier to remedy this evil than in the case of the ribs in the bore. By a simple contrivance the ribs of the shot might be increased in diameter as the grooves were lowered by long usage of the gun. If, moreover, the bore, and consequently the grooves, were formed in a steel tube, and the ribs of the projectile were of a softer metal, there would be no abrasion at all of the grooves.

The writer of the pamphlet is very confident of the success of his plan of straight firing by directing grooved shot along parallel ridges or ribs. He comes to the conclusion that "the motion of the shot within the bore would be perfectly regular, uniform, and straight, and directed truly on the line of aim," and he regards twist rifling as a "make-shift."

But has he well considered the effect of twist rifling in giving to a projectile that rotary motion, which keeps it steady in its line of flight, which compensates any slight deviation from balanced weight, and even tends to check eccentricities of motion, just as the fly wheel regulates the motion of an engine and keeps it at a uniform speed and development of power?

Before it can be predicated that a projectile, issuing from a gun without rotary motion, will preserve its centricity and the line of its course perfectly straight, many comparative experiments require to be made. It is a theory for which the sanction of practice is wanting. All experience tends to prove that to keep a body, which is moving through space or through the air, true to its orbit or course, rotary motion is the natural law. We must, however, do the author of this interesting little publication the justice to say he has displayed great ingenuity of research in investigating the principles which regulate the flight of projectiles, and has opened a question which may throw a new light on the science of gunnery.

MR. REED'S PAPER AT THE NAVAL ARCHITECTS' INSTITUTION.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

Sir,—I was not a little amused to hear my friend Mr. Reed, in his paper on armour-plated ships, read at the late meetings of the Naval Architects' Institution, quoting from a paper of mine printed in the "Transactions" of the previous year, on "Jointing and Rivetting Iron Ships," and very adroitly turning my own arguments against myself. You inserted Mr. Reed's abridgement of his paper on the 20th ult., and on the 10th inst. with equal gravity wrote a long leader on the same subject, with still longer quotations from my paper, using the same ingenious device as Mr. Reed had done. The writers of both papers, no doubt, had a good laugh at my expense, as they could have had no graver object in so applying what I had written ; both are perfectly aware that, do their best, they can but bolster-up a bad cause, in which they are not themselves believers—at least, if I may take the writings and arguments of both as employed on former occasions.

But the fact is, the Secretary to the Admiralty and the Controller are at their wits' end to know what to do;* and while both are enlightened men, and see what it must all end in, yet, in the meantime, how to overcome the pressure put upon them by the respectable, practical, old-school men around them they know not, and so iron must be abused and wood upheld for a time at all hazards ; and perhaps nothing showed this more glaringly than my friend Reed's paper. If he really wishes to know my views, and to quote them, let him read back and see some feeble pictures (drawn from nature) by which I have attempted at various times to illustrate how utterly hopeless is the cause of wood, and how absurd it is to cling to a system now so fairly distanced. He will there see—what, by-the-by, he knows as well as I do—something of the effects of dry-rot, of bad fastenings, of straining seams, of quivering stern-frames to which they dare not apply the full force of the engines, and a few more pleasing symptoms which may be cloaked over in the Navy, but which have long since sent wood into oblivion in the mercantile steam marine. There is, however, a real difficulty in introducing iron hulls generally into the Navy, and this is a most convenient peg on which the Admiralty hang their objections, while they steadily and obstinately refuse to try simple means for its removal, though pressed upon them for several years. The fact is, if there were no fouling, the Government could not possibly maintain their ground. It all rests there.

In a more serious tone I would also ask, would a *well-built and well-proportioned iron ship* have gone to pieces so soon, under the circumstances, as did the new ship "Orpheus"? From all I can see, I think not. Iron ships are easily penetrated on rocks, but are tough things to *break up*—"Birkenhead" and "Royal Charter" notwithstanding.

Now, if Mr. Reed wishes to root himself firmly in the confidence of the practical and thinking men of the day, he will throw off the fetters that surround him, and not pledge himself by writing up what he knows cannot stand long, but gradually prepare those whose adviser he now is for the entire abandonment of a system which has long since received its death-blow, and which a powerful body of men in the House of Commons are resolved shall not much longer be shelved.

I feel, after thirty years of consistent advocacy of iron ships, that I need not on every occasion go over the old and threadbare arguments in favour of the system, but may, when occasion requires, openly tell shipbuilders where faults still exist and suggest improvements, and ask all to keep a watchful eye on every point, so that we may reap still greater advantages from the change which is now happily out of the reach of any shafts that its unhappy opponents may still endeavour to launch at it.

Your obedient servant,
John Grantham.

31, Nicholas-lane, London, April 13, 1863.

REVIEW.

The Working of the Steam Engine Explained by the Use of the Indicator; *or, An Exposition of the Best Means of Producing the Greatest Impulsive Effect from a Given Quantity of Fuel; with a Description of the Mode of Expanding Steam, and the Compounding of Engines.* By Joseph Hopkinson. Illustrated with Engravings and Diagrams. 4th edition, enlarged and improved. London: John Weale, High Holborn. 1863.

[Second notice.]

We now come to that part of Mr. Hopkinson's book in which he treats on the use of steam expansively, by means of one cylinder or of two compounded cylinders, and in which he gives directions for the management of the steam engine, boiler, and furnace. Interspersed with the above matters, there are short chapters on throttle valves, metallic packings, cased cylinders, &c. We have very few objections to raise against this part of Mr. Hopkinson's work; indeed, for its popular and clear treatment of the various working steam apparatus, it deserves great praise. The explanation of the principle of expanding steam and its adaptation to various forms of steam engines, is very clear and intelligible, and these chapters are admirably suited for the study of ordinary enginemen and their unprofessional employers.

We will forbear to point out the many outrageous grammatical mistakes that are to be encountered during a perusal of this book ; let it be sufficient for us to say that but in very few instances do these mistakes interfere with the clear understanding of Mr. Hopkinson's meaning. We will also refrain from further allusion to the different attacks of Mr. Hopkinson on Mr. McNaught, Messrs. Petrie and Co., of Rochdale, and on Boiler Associations and their inspectors generally; Mr. Hopkinson gives his reasons, and they are often very good ones. At the same time, we cannot help regretting the want of good taste that leads a man to continually thrust *his* indicator, *his* boiler, *his* safety-valve, *his* equilibrium-valve, &c. &c., before the readers of his own work. Honest criticism is a literary police force ; and it is as condemnable in a literary critic as in a police constable to wink at offences that both are bound to point out.

The author brings forward the patent of Messrs. James and John Roberton, of Glasgow, taken out in 1800, as being an identically similar one to a 1845 patent of Mr. William McNaught, of Glasgow. There are many patents for real inventions that could be matched in a similar manner, by ransacking the old specifications under the law previous to 1852. Mr. Nasmyth's hammer patent was invalid, for a similar reason, all the time he was making his fortune by the steam-hammer. Before Mr. Woodcroft published his patent index, the difficulties of a search amongst the old omnibus patents were of a superhuman character. We certainly concur with Mr. Hopkinson in his remarks on the use, and his strictures on the abuse, of placing an additional cylinder at the other end of a beam engine; and the information and opinions enunciated on the matter by Mr. Hopkinson, are very well stated.

In alluding to the unnecessarily large and often badly constructed boilers that are generally used in the Lancashire districts, the author says, that "It is truly awful to contemplate the force pent up within large boilers from six to ten feet in diameter, and from twenty to forty feet in length. No good reason can be assigned for the use of such *large engines of destruction*; for the quantity of metal contained in these large and unsafe structures, would produce boilers of many times the strength, and of double the power, with a less expenditure of fuel, were they only constructed of a proper form." We believe that the employment of cast steel will also greatly further the use of high pressures of steam and of corresponding rates of expansion. We will take occasion to allude to this important direction of engineering progress.

The author says, at page 233, that "An engine may be quite safe when new, working out a given power; but by continued use the metal, from constant action and reaction, becomes granulated, and less able to resist strain and concussion." This sentence enunciates a somewhat parallel opinion to that in a Paper, read some time ago, before the Institution of Civil Engineers, by Mr. Frederick Braithwaite, C.E. The essay was entitled "The Fatigue of Metals." The mystery that still hangs over the molecular structure of metals would seem to point out that, as yet, inadequate means have been adopted to clear up the influence of the structure of the ultimate atoms of bodies on their powers of cohesion.

Mr. Hopkinson seems to recommend the use of a small high-pressure engine in each room of a mill. This would result in a saving of heavy shafting and gearing required to get up the speeds, and each room would be independent of any other. The system of several small independent engines is already in use in works where no very great regularity of speed is required—such as engineering workshops, rolling mills, &c. We believe that Mr. Nasmyth, of Patricroft, was the first to employ this plan. At present, however, there is no system of steam-engine governor exact enough to render this division and scattering of steam power applicable to cotton spinning. Before Watt's centrifugal governor exerts its influence on the throttle valve an alteration of speed must have already taken place, with a consequent deterioration in the work produced by the spinning machinery. It is evident that the speed of a single large engine must be easier to regulate, than if the same power were divided into several small engines.

We agree with Mr. Hopkinson in his favourable opinion as to the horizontal form of engine, and we are fully prepared to endorse the dictum of a spirited gentleman, "Mr. M——," quoted by the author (Page 272), as "offering any man present (at a meeting in Rochdale), if he was in favour of beam engines, £5, if he did not say, after he had seen both working, that horizontal were superior to beam engines. He would give the £5 as freely as ever he gave a shilling to his wife." At the same time, there is an undeniable tendency in the lubricating matters used in a horizontal cylinder to gravitate to the bottom, leaving the top half exposed. Mr. Richard Roberts, the famous engineer, stated, at a meeting of the British Association in Manchester, that he often found horizontal engines to wear away on the top half of the cylinder. This appeared a paradox to many present. It sometimes happens, if the engine be badly made, that, when the packing rings wear away, the body of the piston touches the lower half of the cylinder, and when the steam leaks past the rings, through the usual slits, for the V's, the whole piston is pressed down on the lower half of the cylinder. The real thing, no doubt, is to have a good hard quality of metal for casting the cylinders; this metal should be distinct from the usual material run from the cupola, and it should be formed of a particular combination of different irons.

In a chapter on cased or "steam jacketed" cylinders (page 306), Mr. Hopkinson points out the liability of the diagram to be vitiated by the steam issuing through any bad joints between the case and the cylinder. A diagram is given as an instance. Another very interesting diagram is given, showing the influence of the use of a jacket on the consumption of steam. Certainly the indicator is the only true and easily available means of getting at the internal action of the steam engine.

It is stated (page 318) that the greatest drawback to the use of the injector consists in the obligation to use *cold* feed water, at a temperature not higher than 80 deg. We believe, however, that it is only necessary to *start* the injector with cold water; the current being once established, it can be continued with hot water. This requires a particular arrangement, which we understand has formed the subject of a patent.

The chapters on the management of the engine, boiler, and on stoking the furnace, are, we repeat, excellent. Mr. Hopkinson says, truly enough (page 325), that a column of mercury is the most exact pressure gauge, and we only hope that he marks out the scales of his indicators by means of this instrument. He also gives an ingenious way (page 334) of clearing the rose of the feed pump, should it become choked, without stopping the pump in getting down the rose. A small pipe and tap are fixed under the bottom clack-valve of the pump, the top of the pipe being open to the atmosphere. When the pump is working the tap is, of course, closed, but on opening it the pressure of the atmosphere will react on the water column in the suction-pipe of the pump. The water between the bottom clack and the rose will thus rush back with a proportionate force, and will blow the dirt or any leaves, &c., off the rose.

In giving, at pages 338 and 339, directions to calculate from a diagram the quantity of steam used by an engine, Mr. Hopkinson knows as well as we do that such an estimation only slightly approximates to the real quantity of steam used. Take, for instance, the case of an engine priming to some extent; what a loss of power and heat there must be, when particles of water are mechanically conveyed by the steam. In reference to some remarks of Mr. Hopkinson's, pages 276 and 277, in which he appears to deny the liability of an engine priming from its being placed lower than the boiler, we may observe that when the boiler *does* prime, it is evident that there is less chance of the steam getting rid of its mechanically combined water when the cylinder is on a lower level. Our attention has been directed to this by a case in our own experience:—Mr. Hopkinson says: "Reasoning on this statement (as to the liability to prime of engines on a lower level than the boilers), it must follow that in locomotives, and other engines where the cylinders are placed below the boilers, the engines must prime, and be subject to breakdowns." There is always a dome for drying the steam of locomotive engines, and also generally a "baffle plate," or perforated plate, placed in the dome to act as a strainer or cullender on the steam. Boilers, however, often prime in an intermittent and scarcely accountable way.

Under the heading of the "Strength of Iron Bars and Boiler Plates," we find some valuable, if not quite original, hints on the construction of boilers. The author points out the injurious influences of punching and "drifting" on the riveted joints of boiler plates. He also advocates heating the plates before bending; for, besides thus preserving the tenacity of the plates, "if there were any flaws in the metal, these would sooner show in the plate when in a heated state." The advantages of boring the rivet holes are also pointed out. Mr. Hopkinson lays the blame of a boiler explosion at the door of the Manchester Association for the Prevention of Boiler Explosions. The boiler referred to, one belonging to Messrs. Hargreaves, of Accrington, was tried by means of the hydraulic test, at the instance of the inspectors of the association. The boiler was tested to 70 lb. to the square inch, while the original extreme working pressure was a little under 40 lb. to the square inch. In about three months after the hydraulic test had been applied, the boiler exploded. Mr. Hopkinson is convinced that the testing had injured the structure, causing a gradual deterioration. The flues had been strained and distorted by the test.

In a voluminous appendix at the end of the book Mr. Hopkinson has given a great variety of tables; most of the tables, in fact, that are found in engineers' pocket-books. There are also some recipes "for cements for joints, to be purchased of Messrs. Hopkinson and Co." Amongst these various tables, Mr. Hopkinson might as well have given a table of the heights and corresponding pressures of the mercury barometer, thus enabling the possessor of the work to estimate the effect of the weather, or rather of the barometric pressure for the time being, on the vacuum in the condenser, and its resulting quality of the vacuum shown by the indicator diagram. Mr. Hopkinson probably does not consider this necessary, as the average pressures on both sides of the piston are not affected by the height of the barometer; and as regards the quality of vacuum itself, he will probably say that the amount is too slight to be noticed; but he here again shows a want of due appreciation of true scientific accuracy.

VISIT OF THE LORDS OF THE ADMIRALTY TO THE ATLAS WORKS, SHEFFIELD.

On Thursday, last week, the Lords of the Admiralty paid a visit to the armour-plate works recently erected by Mr. Brown, in Sheffield. The *Times*, in its account of the visit, gives the following particulars:—The visitors were conducted through the extensive new and old mills and workshops, where some 3,000 hands were busily engaged in melting, bending, hammering, and twisting great masses of seething iron into every conceivable form its stubborn nature could be made to take. It was really a wonderful sight. On every side, amid thick smoke and deafening clamour, the blazing rites of Moloch—the furnace God of old—were being celebrated. Great furnaces, blaring in the fierce white glare which shone from their crevices, were stuffed to the mouth with monstrous cranks and shafts, and uncouth bosses of red-hot metal. Every now and then some one of them was opened, with a flash that filled the smoky atmosphere with a glare as from snow, and a mass of metal, seething and sputtering in a blaze of sparks, was dragged off and moulded, like so much wax, under the blows of steam hammers that made the earth tremble and the whole building to jump and chatter under the stroke, as if from the shock of a little earthquake. It was wonderful to see the skill with which the groups of workmen, uniting all their individual exertions in a series of violent efforts like a weird species of dance, contrived to hedge and move about the great masses on the anvils, so that the hammer struck only where and how they chose. While the heat lasted in the mass, and that was for a long time, they never paused or slackened in their work, and though literally almost scorched by their proximity to red heaps they kept on toiling till the work was done, and the lump that a quarter of an hour before was almost melted iron was picked up by some huge crane that came travelling along the smoky walls, and carried off, glowing through the gloom, a finished piece of work. At other places there were tilt and lever hammers, wearying the very air with the clattering din of their tremendous strokes. At others great ingots of steel were cast by the Bessemer process, small plates were rolled and roughly cast aside in great red slabs to cool, or hurried backwards and forwards in iron trucks, scorching even the hardened workmen out of their tracks as they came burning past. On every side there were furnaces and smoke and red-hot metals, while in out-of-the-way nooks men in steel caps and wire vizors, and cased below in rough steel leggings, like jack-boots of iron, fought in a crowd like so many salamanders round some rough mass that was dangerous in its fierce heat, and which sent back aggressive spurts of red-hot metal in return for every blow. Such fiery combats as these were going on in all directions; the "Sheffield carpet" of the factory —iron plates—was hot and painful to the feet; the air was arid with a sulphury warmth that was like the glow of an overheated stove. When we have said thus much, and added that there were roaring pipes of steam mounting into the air side by side with great iron trumpet-shaped piles of chimneys, out of which jets of red flame roared and flapped into the smoke above like gigantic flambeaux; that lower down long lines of lathe bands flew noiselessly in all directions, and that the background was filled in with glimpses of ponderous fly-wheels whirling their arms through the smoke and turning rolling mills or lapping hammers, or shearing down with noiseless might the great lumps of iron that were brought in to be cut up,—we have said enough to indicate the view which met visitors on their first introduction to this glowing scene of industry. Though not the first, yet by far the most important process which their Lordships were shown was the operation of rolling the great plate—by far the largest single plate that has ever yet been rolled in the world. This took place in what are called the New Mills of the Atlas Works, which were used on Thursday for the first time, and where great ranges of furnaces have been erected, with their mouths opening on the iron tramway which leads direct to the double rollers through which the plate passes. One may guess at the solidity required for mills of this kind when it is stated that some of the rolls used at this mill on Thursday have a first foundation of no less than 60 tons of solid iron, resting on masonry carried far below the earth. The rolls themselves are 32 in. in diameter and 8 ft. wide, and are turned by an engine of 400-horse power, putting in motion a fly-wheel large enough apparently to make a world rotate if only well balanced on its axis. A powerful screw, applying its force through compound levers, allows the distance between the rollers to be adjusted to the fraction of an inch, so that the plate which on its first rolling is forced through an interval of, for instance, 12 in. apart, is on its next wound through one of 10, next through one of 8, and so on till the required thickness has been carefully and equally attained by tremendous compression through every part of the metal. There were a great many visitors to see the rolling of this formidable mass, which was fortunate, as one would certainly be frightened to witness the terrible process alone. After some delay and quick glimpses made by the most hardened workmen, who, rushing up to the door of the furnace, got a half-blinded glance into its white interior, it was decided that the mass was ready, for, strange as it may seem, an armour-plate requires more than mere heating, and has to be cooked and watched in its cooking with as much care as if it was an omelette, and the plate that is drawn before it is "done to a turn" generally remains a permanent ornament of the unlucky manufacturer's workshop, which no one will have at any price. When at last this eventful moment had arrived on Thursday, the door of the furnace was slowly raised, and a colossal pair of pincers, with very long handles fastened to a chain drawn by machinery, was swung in. For an instant some men rushed forward, and, shielding their faces from the deadly heat that shot from the furnace, adjusted the bite of these forceps on the plate, and then ran back as the chain began to tauten, and the great inmate of the blazing den was slowly dragged forth on to the long iron trucks in front of the door, and there lay in its huge length and thickness a mass of living fire, which none could approach, or scarcely even look at, so fierce was its glow and terrific heat. The chains that should have pulled it forthwith to the rollers were too slack, and then arose shouts, and cries, and commands, as the men did battle with this mass of fire, coming so near it in their attempts to gather up the slackened chains that one literally almost expected to see them fall scorched and shrivelled on the ground. In its great glare they fought and struggled with the chains till at last all was adjusted, and the great pile of angry fire began to move slowly downwards towards the mills, the men following it with hoarse shouts and directions, now hid in steam, as buckets of water were dashed over the mass, and the next moment standing in an atmosphere of white light, to which the light of the day around was mere dusk. The rollers did not bite directly the the mass came to them, and when they did the engine was almost brought to a standstill by the tremendous strain upon it; but at last the soft plate yielded, and the rollers seemed to swallow it as they wound it slowly in, squeezing out jets of melted iron like squirts of fire that shot about dangerously as the pile was compressed from 19 in. to 17 in. thick by the irresistible force of the rollers. *Ce n'est que le premier pas qui coute*, and the victory was certain when the mass had once passed through the mill, and both visitors and workmen gave a tremendous cheer at the success. From this time it was kept rolling backwards and forwards, the workmen sweeping from its face the scales of oxide that gathered fast upon it with long-handled besoms, that, though soaked in water, caught fire and blazed up as fast they were used. With every time it was passed through, the rollers were screwed closer and closer together, as we have already mentioned, till at the end of about a quarter of an hour after leaving the furnace an almost melted mass, it was passed through for the last time, and came out opposite the furnace door it had so lately left, no longer shooting forth spiteful sparks, but shorn of half its heat, subdued, and moulded to its proper form—a finished armour-plate, weighing 20 tons, 19 ft. long, nearly 4 ft. wide, and exactly 12 in. thick throughout from end to end. This is the most signal triumph that any rolling mills have yet achieved.

Other smaller plates were then rolled with a quickness and certainty that proved the skill already gained in this new and most important branch of manufacture. One plate was 17 ft. long, by 4 ft. broad, and 5½ in. thick; one 19 ft. long, by 4½ ft. wide, and 4½ in. thick; one we have already alluded to, 41 ft. long, by 3 ft. 10 in. broad, and 4½ in. thick. A lesser plate was also rolled 18 ft. long, 5 ft. wide, with a thickness of 6 in. on one edge and 3 in. on the other. The method of converting cast iron by the Bessemer process into the tough soft Bessemer metal, a combination of the qualities between soft steel and tough wrought iron, was next shown. It is needless now to enter on a description of the very beautiful and very terrible process, to witness, which the metal goes through in the converter as it is stimulated to a white heat by the passage of the air blown by force-pumps upwards through the mass. No fireworks can surpass the brilliancy of the display this process affords as it approaches its completion, and the stream of violet flame and clouds of burning sparks pour from the mouth of the converter as from a gigantic squib. Nor is it necessary here to enter into a detail of the now well-known process, which was a subject of such controversy a few years since, but which is now being so generally and advantageously adopted throughout England and the Continent. Suffice it to say that in twenty minutes from the time of putting in the charge of cast iron, it was, without any expenditure of labour, poured out into the mould an ingot of soft, tough steel, weighing three tons. This metal, after undergoing hammering, is now most extensively used for steel rails at stations, points, and junctions, where the wear is great, and in these trying situations it seems almost indestructible. A great deal has also been used in making Blakely rifled guns in this country for both Federals and Confederates. These are the ordnance which the Americans always speak of as Parrott guns, and by them they are more highly prized than those of either Armstrong or Whitworth. Yet it was stated that the Ordnance Select Committee have refused even to try these guns at Shoeburyness. After these processes were over, and the various planing and filing shops had been duly examined, the visitors were entertained by Mr. Brown at a most sumptuous *dejeuner*.

THE FOULING OF SHIPS.

The following is the substance of a paper read before the last general meeting of the Institute of Naval Architects, "On the Protection of Iron from Oxidation and Fouling," by Mr. W. J. Hay, chemical lecturer of the Royal Navy College, Portsmouth:—

The author remarked that a few years back the disadvantages arising from the oxidation and fouling of iron, and the consequent necessity for docking, as well as a loss of speed, almost led to a determination on the part of the Admiralty to discontinue the construction of iron sea-going ships. But at a time when the executive were debating about the sale of the whole of the iron ships the results of several experiments became known. A preparation of oxide of copper had been tried upon the "Undine" and several other vessels, and answered so well that the Government decided upon retaining those iron vessels which they had not sold. The author had tried many experiments that had occurred to him, but none stood the required tests so well as oxide of copper. An experiment was tried on the "Rocket" in May, 1845. On examination the results were found so satisfactory that, at the suggestion of Admiral Sir Hyde Parker, she was coated in June, 1857, with alternate stripes of red lead and copper composition, and when docked about the middle of 1848, she presented a curious appearance, many of the red lead patches being corroded and having weeds 3ft. or 4 ft. long; while the patches of composition were generally covered with a little slime, but there was neither weed nor corrosion on them. A second experiment was made in September, 1845, on H.M. yacht "Fairy." Three different kinds of composition were then tried. With reference to the first two—one by a Mr. Owen, and the other by Baron Wetterstedt—oxidation had gone on very rapidly, while the third, which consisted of a composition of pitch, naptha, and copper oxide, chemically prepared by the author, no oxidation had taken place, and the only defect perceived in it was a partial flaking off occasioned by its being put on the bottom while in a wet state. Another experiment was tried on H.M. ship "Recruit," in April, 1847. The copper oxide preparation was put on the port side, and burnt linseed oil and red lead on the starboard side, excepting a space amidships, 4 ft. square, to which the oxide of copper preparation was applied. On her return to the Tagus, the port side was found to have no adhesions, except about one dozen small barnacles; while the starboad side, excepting the space 4 ft. square, was covered with bushels of the *Lepus Anatifera*, or duck barnacles. Of all the various compositions tried, oxide of copper had, up to the present time, been unequalled as a protector of the iron. The next best materials for protecting iron were the waterproof glue, and a varnish of foreign asphalte and mineral pitch dissolved in rectified naptha; but these required great attention to the quality of materials, and also to the application of them. The basis of the anti-fouling preparation, which had for years past been used in H.M. Service upon the author's recommendation, was sub-oxide of copper. The oxides of copper used for this purpose were the scales separated from the sheets of copper in the "pickling" process. These scales, after being pulverized, were mixed with a varnish made of vegetable pitch and rectified naptha. The author wished it to be understood that the protective coating, when used with the oxide of copper anti-fouling composition, was not intended merely to act as a non-conducting medium to prevent galvanic action, but to protect the iron from chemical action resulting from the action of air and sea-water on the iron. It appeared to him that this action was little understood, judging from printed statements which occasionally appeared, and which attributed the loss and corrosion of iron to galvanic action of copper preparations. The copper oxide paint could not act as a galvanic agent, as every particle of oxide of copper was insulated by the oil or varnish in which it was enveloped, and unlike preparations of a metallic character, which had been frequently tried, and required oxidation previous to combination with chloric acid, the oxide of copper was, as soon as uninsulated, ready for chemical combination with the elements of the sea-water. The author admitted that one great difficulty had existed since the first use of copper oxide—that of requiring careful supervision in its application; for when the varnish was made too thick it became locked up, and much of its usefulness was destroyed in not coming in contact with the sea-water; and, on the other hand, when the varnish was made too thin, the oxide sank to the bottom, and, if the mixture were not continually stirred, it got left there, and did not reach the ship. He had now, however, he stated, succeeded completely in suspending the copper oxide during its application. He takes the puce-coloured or sub-oxide of copper and roasts it till it takes up another equivalent of oxygen and is converted into black oxide. This is then boiled with linseed oil until it assumes its original pure colour as sub-oxide; the oil so treated becomes a quick drying oil, and is capable of suspending a large amount of copper oxide. In his plans for the anti-fouling composition, the author included the application of zinc plates inside and outside the hull of the ship to prevent oxidation from abrasion or other causes. There were numerous parts of iron ships-of-war which required chemical supervision, as not only should every metallic fitting electro-negative to the iron be insulated, but every piece of timber should be insulated, especially in the bilge; for when wood decayed in contact with iron and sea-water it produced sulphuretted hydrogen. Certain woods, however, were less liable to decay than others when in contact with iron, and among them were teak and stink-wood. In conclusion, the author alluded to the statements made respecting the foulness of the "Warrior's" bottom. He said that after she had been out of dock nine months, she had no oxidation whatever on her bottom, although she was coated with the greatest expedition, it being then thought that her presence would be required in American waters.

COWAN'S GUN THIMBLE.

Fig. 1.

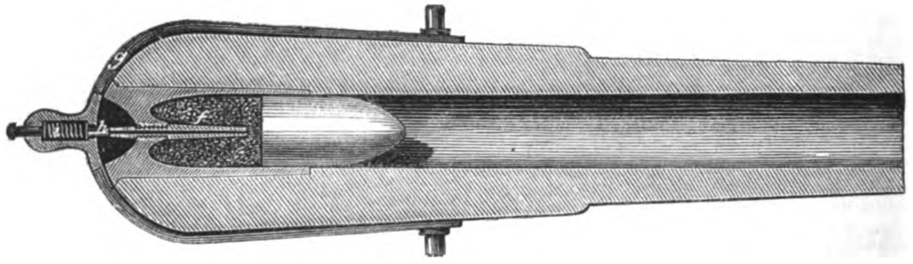

Fig. 2.

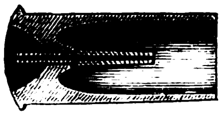


COWAN'S CARTRIDGE CASE OR GUN THIMBLE.

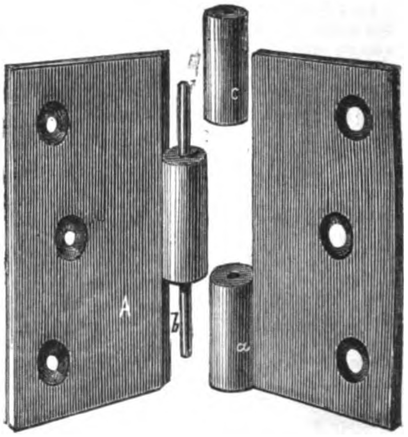
The above engravings illustrate a cartridge case or thimble recently patented by Mr. B. F. Cowan, of Euston-square. The thimble is made of any suitable material, and so formed as to fit into the breech end of a gun, as shown at fig. 1. It is held in the gun by a strap or other contrivance: the strap is shown with a projection or knob, in which a spring is inserted to keep the rod or pin upon the nipple. The thimble has slits cut in it, as shown at fig. 2. These slits make the sides of the thimble more or less flexible, so that the bore of the thimble towards its open end can be expanded by an internal or contracted by an external force. This thimble contains the whole of the charge of powder or other explosive material, and may contain also, as may be found convenient, the whole or the rear portion of the projectile or shot. When the explosion takes place, the gases thereby generated expand the thimble, and cause a proportionate amount of frictional pressure against the breech chamber, that is, the inner surface of the sides of the gun surrounding the thimble, so that the expansive force of the ignited charge is employed to counteract its tendency backwards. The ignition of the charge may be effected by the action of the spring, driving the pin or striker upon the percussion cap on the nipple.

AN IMPROVED STEREOSCOPIC INSTRUMENT.

At a recent meeting of the Franklin Institute, United States, Mr. E. G. Chormann exhibited an improved stereoscopic instrument. It consists of an outer and an inner casing, and a frame; the inner casing sliding within the outer one. To the front edge of the frame, which slides into the inner casing, is hinged two arms, each of which is provided with a ring for holding a lens. When the instrument is to be used, the frame is drawn from the inner casing as far as possible, without entirely removing it therefrom, and the arms turned out so as to be at right angles to the frame, the picture being secured to the outer case by a flat spring, which holds it against the the same. The glasses may be applied to the eye as in the ordinary stereoscope, and the adjustment made by sliding the inner case back and forth within the outer one, until the proper focus is obtained. When not required for use, the arms holding the lenses may be folded together within the frame, and the latter pushed into the casing; the whole being thus condensed into a compact form of such dimensions as to be contained within the vest-pocket without inconvenience to the wearer.

ARCHER'S PATENT HINGE.

The hinge here illustrated represents one of those devices which are very useful in a great many cases. By the arrangement of the parts with relation to each other, the hinge can be used either at the right or left hand of a door. The construction of it is very simple, and is clearly explained by the engraving. One leaf of the hinge A has the screw-holes countersunk on both sides. The joint in which the pintle *b* works, extends but a short distance from the end and fits over the pintle when in its natural position. The small cylinder *c* is intended to be slipped over the pintle also, thus making the connection between the several parts complete. When necessary, the change from right to left hand can be effected instantaneously by simply removing the loose cylinder and turning the leaf A upside down from its former position. The advantage of such an arrangement as this will be readily appreciated by builders and other interested in such matters. This hinge is the invention of Mr. G. W. Archer, of Ipswich, Mass.



ON ALUMINUM BRONZE.

Lieut.-Colonel Strange has communicated to the Royal Astronomical Society some interesting observations on the use of aluminum bronze as a material for the construction of astronomical and other philosophical instruments. Col. Strange remarks that, "the qualities of most importance in instrument making are—(1) tensile strength; (2) resistance to compression; (3) malleability; (4) transverse strength or rigidity; (5) expansive ratio; (6) founding qualities; (7) behaviour under files, cutting tools, &c.; (8) resistance to atmospheric influences; (9) fitness to receive graduation; (10) elasticity; (11) fitness for being made into tubes; (12) specific gravity."

Tensile Strength.—The mean of experiments made by Mr. Anderson at the Royal Gun Factory, Woolwich, shows that the average breaking tensile strength of aluminum bronze is 73,185 lb. per square inch, while that of gun-metal is 35,040 lb., the ratio being rather more than two to one in favour of aluminum bronze.

Resistance to Compression.—Experiments made by Mr. Anderson show that no effect was perceptible until 9 tons 2 cwt. per square inch was applied, when the specimen gave .006 of an inch; on removing the weight an elasticity of .001 was observed, giving the first permanent compression as .005 of an inch. The ultimate amount of compression applied was 59 tons 2 cwt. 1 qr. 4 lb. (132,416 lb.), under which the specimen became too much distorted to permit of more weight being applied with any true result.

Malleability.—Mr. Anderson states that, "the qualities of this metal for forging purposes would appear to be excellent; with the exception of the part heated to a red-heat in the shade, all show that it is a good workable material under the hammer almost up to the melting point." Col. Strange adds, that there were specimens exhibited in the Industrial Exhibition at London which showed that the alloy could be drawn out under the hammer almost to a needle point.

Transverse Strength, &c.—Messrs. Simms found by experiment that aluminum bronze was 3 times more rigid than gun-metal, and upwards of 44 times more rigid than brass; and, in regard to its *expansive ratio*, they found this alloy less affected by change of temperature than either gun metal or brass—a little less than gun-metal, and much less than brass. Its *founding qualities* are such that it produces admirable castings of any size. It does not clog the file, and in the lathe and planing machine the tool removes long elastic shavings, leaving a bright, smooth surface. It can be worked with much less difficulty than steel, and, notwithstanding its greater cost, the Messrs. Simms think that screws made of it would in the end prove less expensive than steel. It tarnishes less readily than any metal usually employed for astronomical instruments. It is remarkably well fitted to receive graduation, as it takes a fine division which is pure and equable, surpassing any other *cast* metal in this respect. Col. Strange remarks that in its elasticity it is said to surpass even steel, and it would therefore appear to be the most proper material for the suspension springs of clock pendulums. Regarding *its fitness for being made into tubes*, it can be soldered with either brass or silver solder; it can be rolled into sheet metal, and it can be hammered and drawn. Gun-metal does not admit of being rolled, so that hitherto the tubular portions of telescopes and other instruments have been made almost exclusively of yellow brass, an alloy very deficient in rigidity. The *specific gravity* of the alloy containing 90 copper and 10 aluminum is according to Messrs. Bell, 7·689, very nearly that of wrought iron.

Col. Strange adds, "It appears, from these experiments and from the concurrent testimony of those who have given it a fair trial, that the 10 per cent. aluminum bronze is far superior, not in one or some, but in every respect, to any metal hitherto used for the construction of philosophical apparatus, and that for such purposes it may be employed in the dimensions that would be proper in the case of cast steel. All parts which would otherwise be made of steel may with perfect safety, and even with advantage, be made of the new alloy, particularly such parts as bolts, and fixing, tangent, and micrometer screws. Its hardness and comparative inoxydizability point it out as peculiarly adapted for pivots, axes, and bearings. If employed for receiving the graduation of circles, the necessity for inlaying another metal will be obviated, by which two advantages will be gained: the hammering which forms part of the operation of inlaying, and which, more or less, must cause unequal density and tension in the circle subjected to such treatment, will be dispensed with; and the effect of inequality of expansion, in the circle and the inlaid strip, will no longer be a cause of apprehension. With respect to the due visibility of divisions cut on this metal, opinions will perhaps differ. I can only say that I should be well content to observe with them."

This alloy has been selected by Col. Strange as the most appropriate metal for the construction of the large theodolite for the use of the Trigonometrical Survey of India. The horizontal circle of this theodolite is three feet in diameter, and the effect of using this alloy will be to keep the weight of the instrument within reasonable limits, notwithstanding its possession of means and appliances not hitherto bestowed on such instruments. In the manufacture of the alloy, Col. Strange says that extremely pure copper must be used; electrotype copper is best, and Lake Superior copper stands next, giving an alloy of excellent quality. The ordinary coppers of commerce generally fail, owing, it is said, to the presence of iron, which appears to be specially prejudicial. Further, the alloy must be melted two or three times, as that obtained from the first melting is excessively brittle. "Each successive melting, up to a certain point determined by the working, and particularly the forging properties of the metal, improves its tenacity and strength. It is probable that after several meltings there will remain in combination with the copper a somewhat smaller proportion of aluminum than 10 per cent. The present price of English-made 10 per cent. aluminum bronze is 6s. 6d. per lb. This is four or five times that of gun-metal, but a much smaller quantity of the new alloy than of gun-metal will give the same strength; and when it is considered how small a ratio the cost of material bears to the cost of workmanship in refined apparatus, it will be found that even at the present price of the new alloy its cost is not prohibitory, whilst the advantages attending its use promise to outweigh the increased expenditure."—*L. E. and D. Phil. Mag.*, [2], xxiv., p. 508.

C. Tissier, director of the aluminum works at Rouen, shows that one per cent. of aluminum in copper makes the latter more fusible, giving it the property of filling the mould at casting, at the same time preventing it from rising in the mould. The action of chemical agents upon it is also weakened, and the copper gains in hardness and tenacity without losing its malleability, thus producing an alloy which has the malleability of brass, with the hardness of bronze.

In transverse strength this alloy was found to be more than twice as rigid as either brass or copper. Tissier also finds that one part of aluminum, added to bronze consisting of 96 copper and 4 tin, gives an alloy of a fine colour, of remarkable homogeneity, of great hardness and malleability. During casting, this alloy does not oxydize at all, and it is therefore free from the oxyde coating with which ordinary bronze castings are covered. The transverse strength of the castings of this alloy Tissier finds to be two and a half times that of the original bronze, and that of the hammered alloy is four times as great as that of bronze. Ordinary cannon bronze, 89 parts copper and 11 tin, has the same transverse strength as castings of the new alloy. In reference to the hardness, tenacity, and malleability, it is equal in these respects to aluminum bronze, made of 90 parts copper and 10 parts aluminum, and, as it is considerably cheaper, it can with advantage be substituted for this more expensive alloy.—*Polytechnisches Journal*, clxvi., p. 430.

NORTH OF ENGLAND INSTITUTE OF MINING ENGINEERS.

The general monthly meeting was held in the rooms of the Institute, Neville-hall, Newcastle, on Thursday—the president, Nicholas Wood, Esq., in the chair.

The following gentlemen were elected members of the Institute:—Mr. John Nixon, East Colliery, Gateshead; Mr. John Wood, Flockton Colliery, near Wakefield; Mr. Thomas Cookson, Pargate Colliery, near Rotherham.

The President stated that the Council had been engaged that morning in endeavouring to make some arrangements relative to the proposed special general meeting of the Institute, to be held at the same time as the meeting of the British Association in August. The sub-committee appointed for this purpose had had an interview with the local executive committee of the British Association, and they had also been in correspondence together, and there seemed to be several difficulties in the way of the meeting being held after the same manner as at Birmingham, as was originally proposed. The Council would lay a special report before the members, but the substance of the recommendations might be stated as follows:—That a circular be issued to all the members of the Institute, informing them that the rooms of the Institute would be open for them and their friends during the meetings of the British Association; and that special meetings of the Institute would be held every morning before the openings of the sections of the British Association, so that members not residing in this neighbourhood would thus meet the resident members of the Institution, several of whom are connected with the executive of the British Association, and could receive from them all information relative to the meetings and excursions. Also, that all the papers which fall within the scope of the sections, and which may be prepared by the members of the Institute to be read at the special general meeting, and which would really include nearly all classes of papers, would be read before the sections of the British Association, and afterwards discussed at the usual generaal meetings of the Institute, and printed in their Transactions. If any of these papers did not fall within the scope of the sections, these could be read on the Saturday after the closing of the meetings and excursions of the British Association. He hoped that these arrangements would have the effect of inducing many of their distant members to attend the meeting of the British Association, who might not otherwise have done so.

SAFETY OF THE DAVY LAMP GAUZE.

The President then introduced the subject of the "Safety of the Davy Lamp Gauze," to which he had briefly alluded at the last meeting. His attention had been drawn to the subject by Mr. Greenwell, who had visited a colliery where they were in the habit of heating all their lamp gauzes red-hot previously to using them, to prevent their "exploding the gas should they become red-hot in an inflammable mixture." The subject was one of very deep importance, and he (the President) had since made one or two experiments, by inserting new lamp gauzes into the interior of a short red-hot pipe, when explosions occurred from volatization, and subsequent inflammation of the oil attached to the gauze. He had tried, in a similar way, gauzes which had been thoroughly cleaned and brushed, and also others after having been steeped in and thoroughly washed with stony solution of alkali, and the same results followed. It seemed to him, therefore, probable that the oil was contained in the pores of the iron itself, introduced probably in the process of wire drawing. He thought that the subject should be thoroughly investigated. Several explosions had occurred where safety lamps were in use, and which had never been satisfactorily explained. Careful experiment should be made further to prove the liability of a red-hot gauze to explode an inflammable mixture, and the circumstances under which this could occur; and if it be found that this liability really does exist, then remedial measures should at once be sought for, and adopted. Some years ago, he (the President) made several experiments on the safety lamp, the results of which had appeared in their Transactions. The gas was on several occasions exploded by putting the lamp rapidly through it, after the gauze had attained a high temperature; and it was quite possible that the explosion was caused by the co-operation and subsequent ignition of the oil attached to the gauze, and not to the passage of flame through the meshes of the gauze; it would be well if these experiments were repeated to determine this. He thought the matter might very properly be left in the hands of the "Experimental Committee" to arrange and carry out the necessary experiments; of course, any other member who might wish to be present at the experiments could attend.

A resolution to this effect was then agreed to.

VENTILATION OF THE HIBERNIA COLLIERY.

The discussion on Mr. Atkinson's paper, "On the Comparative Efficiency of Two Modes of Ventilating the Hibernia Colliery in Prussia," was then opened.

The President explained that the Hibernia Colliery was situated in the Ruhr Valley, in Prusssia, and the seams there lay at a very great angle, and are much distorted. The Inspectors of Mines in Prussia had desired the proprietors of this colliery to drive an extensive level stone drift from the extreme side of the workings, so as to carry the return air into the shaft at this level, in place of bringing it down to the level of the ingate of the upcast shaft. His (the President's) opinion had been taken professionally, and it entirely concurred with Mr. Atkinson's, whose valuable calculations would be laid before the Prussian authorities. It should be borne in mind that on the Continent the minerals all belonged to the Goverment, and the Inspectors of Mines thus acted as lessees' agents, and took cognizance of the methods of laying out and working the collieries, as well as of their safety.

COAL-CUTTING MACHINE.

The discussion on the paper "On Messrs. Donnethorpe, Firth, and Hedley's coal-cutting machine," by Messrs. John Daglish and Lindsay Wood, then followed. The President stated that this mode of working coal deserved attention and investigation; he hoped that some of the coalowners in this district would take the matter in hand.

—Mr. Atkinson, inspector of mines, alluded to the very brilliant sparks given off by this machine, when the pick came in contact with the iron pyrites; this should be investigated.

VENTILATION OF UNDERGROUND BOILERS.

A paper on this subject, by William Armstrong and John Daglish, was then read, of which the following is an abstract:—

In a previous paper, the subject of supplying "Ventilating Furnaces" with intake instead of return air was brought before the Institute, and instances were given where its application had been attended with marked success. Under certain circumstances, however, as where high shaft velocity obtains, there are objections to its universal introduction. These objections, however, do not apply to underground boilers, their fires must be supplied with air of a higher relative density, in order to obtain a powerful draught. Numerous experiments prove that, under the ordinary application, nearly 10,000 cubic feet of intake air are required for the efficient supply and ventilation of each boiler, distributed as follows—viz., 2,000 cubic feet below and through the fire, 1,000 through the coolers on either side of the boiler, and 5,000 through the boiler-house; of these only the first 2,000 are absolutely required, at the higher density, for the purpose of inducing rapid combustion. The writers advocate placing the boiler in the return; and allowing the return current free access over and around the boiler and coolers, and confining a current of intake air by means of pipes, entering below the fire, where its higher density would be required. This method is now in successful operation. In some of the larger and deeper mines, in which as many as five boilers are employed, the saving of even 5,000 cubic feet per minute per boiler would be attended with most beneficial results to the ventilating current of the mine.

C. W. WILLIAMS'S IMPROVEMENT IN STEAM BOILERS.

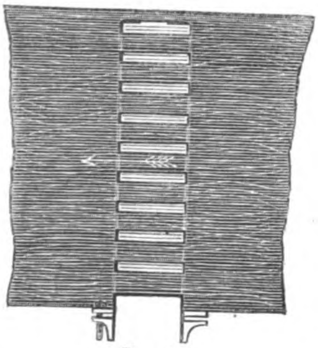

Fig. 5.

C. W. WILLIAMS'S IMPROVEMENT IN STEAM BOILERS.

A **patent** has been obtained by Mr. C. W. Williams, of Liverpool, for an improved means of increasing the evaporating effects of steam boilers. The invention consists in substituting for the ordinary long tubes or flues employed in locomotive, marine, and other steam boilers, sets or series of short tubes or flues of a circular, rectangular, or or other form, at short distances apart, each set or series being fitted into tube plates or face plates like those into which the long tubes aforesaid are inserted. The object of this arrangement is to increase the number of tube plates or face plates against which the flame and hot gases generated in the furnace strike, as in ordinary boilers. The tube plate or face plate surface, exposed to the direct action of the flame and hot gases, is much more efficient than the interior surface of the tubes themselves in transmitting heat to the water within the boiler.

The invention will be better understood on reference to the accompanying engravings. Fig. 1 is a plan of a series of these short tubes, each of which is about two to four inches in diameter, like ordinary tubes, but only eight to ten or twelve inches in length or thereabout, according to the space allowed for their insertion. Each series of tubes is inserted into and between two vertical face plates. Thus the heated current from the furnace passing through one set of these short tubes strikes with a direct action against the next face plate in which the second series of short tubes is inserted, and so on in succession through the remaining series, whatever may be their number.

In place of circular or cylindrical tubes, a series of rectangular short flues may be employed, as shown in fig. 2. Each series of flues is inserted between two face plates, as above described with reference to the tubes. There are spaces between the several series of flues or tubes, and which spaces in succession are open to receive the current of heated products from the furnace, the current from one set of such tubes or flues crossing this space and striking with direct action against the face plate in which the succeeding series is inserted, and so on. In the case of short boilers, where it is necessary to take up the heat in the shortest time and space, and with the view of enlarging the heat-receiving area of each succeeding face plate, the tubes or flues are made of a cone or tapered shape, instead of cylindrical or parallel, thus enlarging the orifice of the outgoing current from each tube or flue, and the heat-receiving area of the face plate against which the heated current is to strike.

Fig. 3 represents a portion of a boiler fitted with cone-shaped or tapered tubes or flues.

In furtherance of the same object, and particularly in short boilers, the several series of such tubes or flues may be so placed that the exit end of each, instead of being opposite and in the direct line of the succeeding tube or flue, shall be opposite the part of the succeeding face plate which intervenes between its tubes or flues, by which means each current of heated products is caused to strike the portion of the next face plate between the receiving ends or orifices of the next succeeding series.

Fig. 4 is a plan of a series of indirect tubes or flues. With the view and for the purpose of facilitating the process of cleaning, repairing, or otherwise, each series of tubes or flues form a distinct and separate vessel, which may be removed or replaced at will, as represented at fig. 5.

BROOMAN'S BORING APPARATUS.

Mr. R. A. Brooman, of 166, Fleet-street, has recently obtained a patent on behalf of M. Leschot, of Paris, for a tool for boring and apparatus for working the same. The invention consists in the construction and employment of tubular tools armed with diamond cutters, to which rotary and advancing motions are communicated. The tools consists of metal tubes with a ring of iron or steel at the working end, into which diamond cutters are fitted; the tube is connected to a shaft by a bayonet joint or otherwise. On rotary and advancing motions being communicated to it, it bores or cuts a circular aperture in the rock, stone, or other material acted on, and receives within it a core or bar of such material, which is afterwards removed. A caoutchouc pipe may be connected to the tube for forcing in water to remove the detritus.

The apparatus for working the tool is mounted upon a carriage on wheels, or on a bed supporting standards, in which bearings are formed for receiving the shaft to which the tool is fitted. Rotary motion is imparted to the shaft through a toothed wheel gearing into a pinion on the driving shaft, which has motion communicated to it from a crank pulley or otherwise. The advancing motion is communicated through a wheel on the crank shaft communicating motion to another wheel on the tool shaft through the agency of an intermediate wheel; one end of the tool shaft is threaded, so that while it revolves the screw at the same time imparts a forward motion to it. For convenience the carriage may run on rails, and may be secured to them by grippers fixed to the carriage.

According to the work it is to be put to, the boring tool may be single or multiple; that is to say, any number may be fitted on one frame, being so arranged as to work at all angles and in all directions, parallel, convergent, or divergent. Motion may be communicated by hand, steam, or other power.

The engravings show the manner in which the simultaneous rotary and forward movements are effected, taking, by way of example, a machine with only one boring tool.

Fig. 1 is a longitudinal section, and fig. 2 a cross section, of a boring tool constructed according to this invention. *a* is a tube of steel or iron, or other metal; *b* is a ring, or crown, carrying on its face several cutters *c*, *c*, being diamonds. This ring is changeable, that is, one ring may be removed and another supplied in its place; it is fixed on the tube by a bayonet joint or otherwise. The tube *a* is supported in bearings, and receives continuous rotary motion through suitable gearing on the driving shaft. The tube has also an advancing motion imparted to it.

Fig. 3 represents an arrangement in which the tool is fixed to a socket moveable round the vertical upright, and capable of being raised or lowered to enable it to be worked at all heights; by means of three bolts, the conical heads of which slide in a circular groove or slot, the tool may also be inclined to bore holes at any angle or in any direction.

The apparatus may be fixed to the frame mounted on a carriage on wheels or roller; the carriage may be secured on rails by grippers, as shown in fig. 4, or in any other convenient manner. At each turn of the tube *a* the cutters *c* bore or cut a circular aperture in the rock or other material acted on, and a core or bar of the material is received within the tube, and is afterwards removed, the tube advances a distance determined by the pitch of the screw thread and by the relative motions of the wheels. A caoutchouc pipe is connected to the threaded end of the tube for forcing in water to remove the detritus, without which the tool would become choked, and channels or grooves may be formed on the exterior and interior surfaces of the ring *b* to facilitate the passage of the water.

Fig. 5 represents an arrangement suitable for

BROOMAN'S BORING APPARATUS.

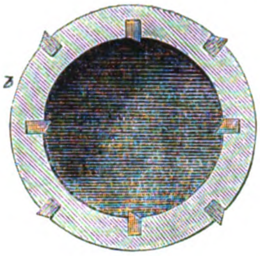

FIG. 2.

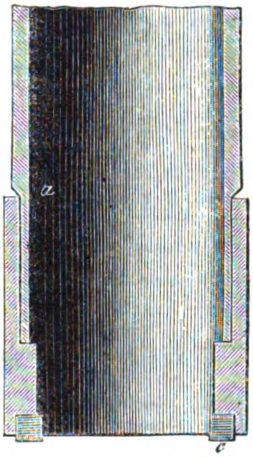

FIG. 1.

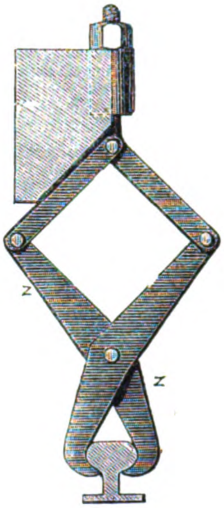

FIG. 4.

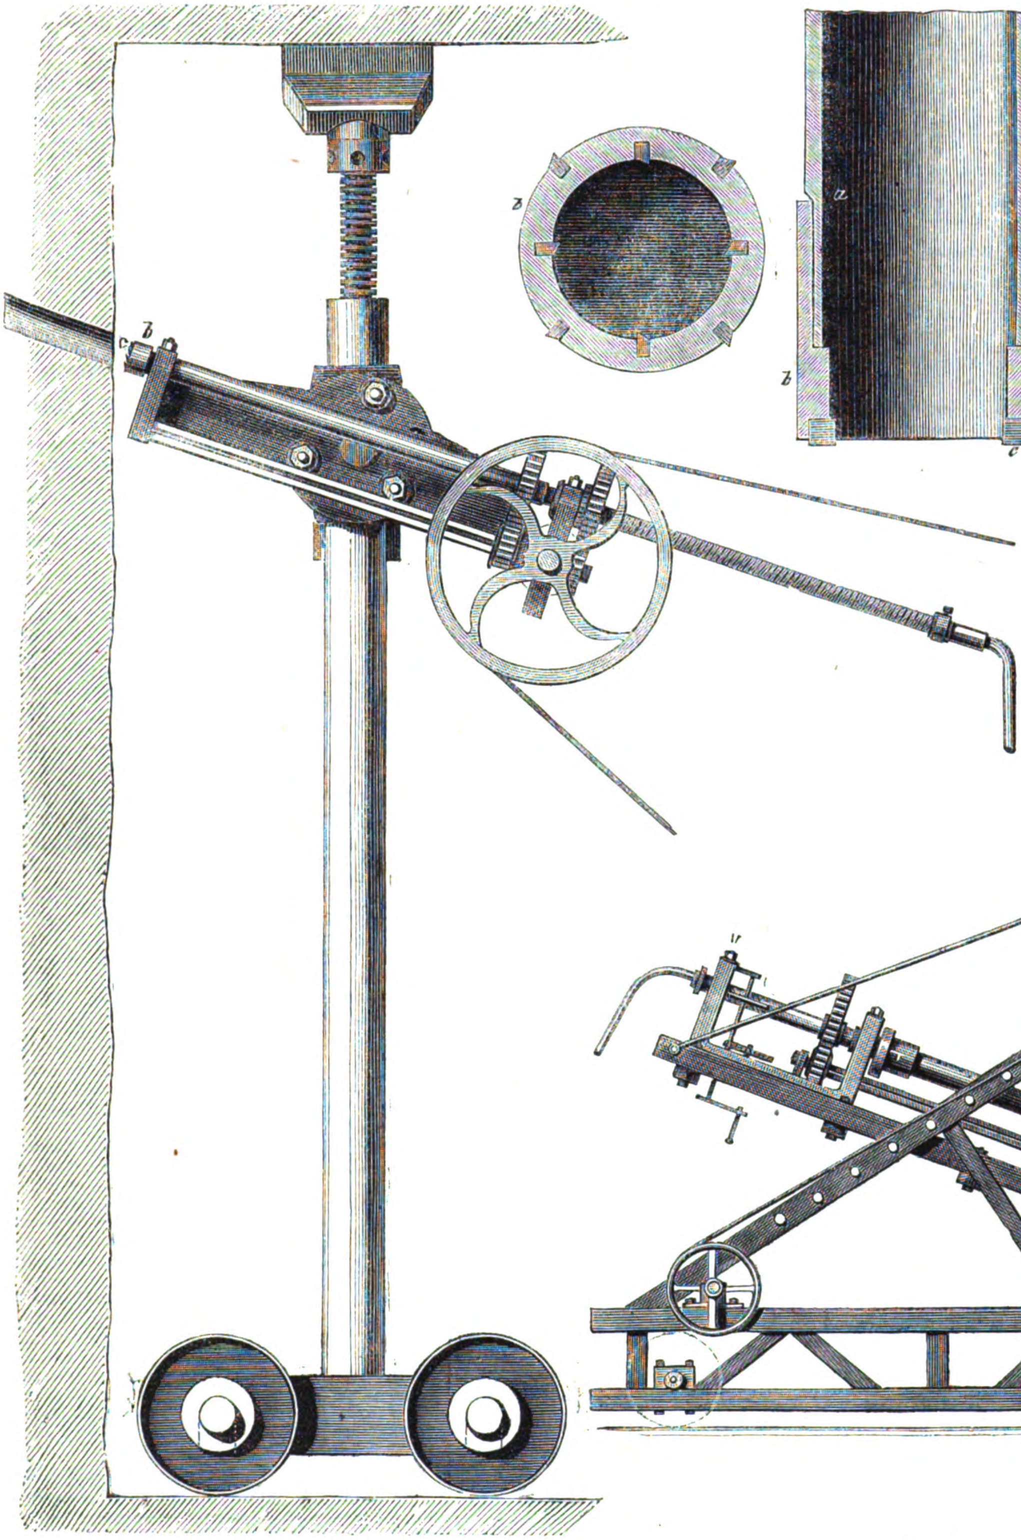

FIG. 3.

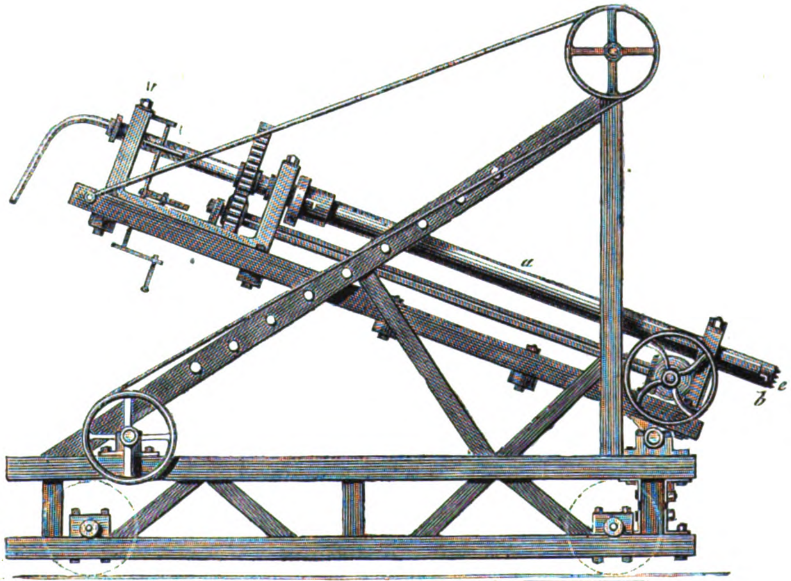

FIG. 5.

boring deep holes of large diameter and in any direction. The motion is imparted by a crank or by a belt passing over a pulley, which, through gearing, gives rotary movement to the tool. The tube *a* has a threaded prolongation fixed to the frame *v*, carrying rollers. The threads communicate rotary movement through toothed gear to a pinion gearing into a rack extending the whole length of the wooden frame which supports the apparatus; the frame *v* thus receives an advancing motion, which it transmits to the tube and cutters. This arrangement allows of the variation of the inclination of the tube.

At a recent meeting of the Franklin Institute, Philadelphia, Mr. Thomas Shaw exhibited a specimen of fractured glass tube, the peculiarity of which consists in the line of fracture, which is in the strongest direction, and instantaneous throughout the whole length, from 10 to 15 ft., without any apparent cause. This does not occur with tubes made in shorter lengths, other conditions being the same. He attributes the cause to the mode of straightening the tube, which is done in this wise. After the tube is drawn out sufficiently, it is held suspended in the air, and revolved until sufficiently cool to permit no further bending. It will be observed that this continual bending, which the above operation causes, must necessarily bring the glass to a state of *torsion* in the direction of the fracture. He has since had tubes made of the same length, in the usual manner, with the exception of cooling and straightening them upon a flat surface, that are free from this evil.

TO CORRESPONDENTS.

The MECHANICS' MAGAZINE is sent post-free to subscribers of £1 1s. 8d. yearly, or 10s. 10d. half-yearly, payable in advance. Post orders made payable to Mr. R. A. Brooman, of 166, Fleet-street, E.C.

Advertisements are inserted in the MECHANICS' MAGAZINE at the rate of 6d. per line, or 5½d per line for 6 insertions, 5d. per line for 13 insertions, 4½d. for 26 insertions, and 4d. a line for 52 insertions. Each line consists of about 10 words. Woodcuts are charged at the same rate as type. Special arrangements made for large advertisments.

To insure insertion in the following number, advertisements should reach the office not later than 5 o'clock on Thursday evening.

Correspondents who wish their manuscripts to be returned are requested to say so.

RECEIVED.—W. M.—M. A. (answered by letter.)—V. P.—A. B.—A. G.—Capt. N.—Ed. W. B.—C. G. B.—T. G.—Com. O.—W. A.—J. V. P.

J. A. H.—The MECHANICS' MAGAZINE and BUILDING NEWS shall be sent regularly.

E. W. B. (Manchester.)—The Magazine is sent regularly. Does the irregularity arise from the local post-office?

J. B.—Thanks for the offer. We have made it a point not to co-operate with patentees in such matters.

TYRO.—The best work on locomotives is Mr. D. K. Clarke's. It is published by Blackie and Sons, and it costs about £4 10s.

G. M.—We know of no good work on the subject.

T. S. (Sheffield).—We cannot insert your request. You can purchase some loadstone at Knight's, Foster-lane, Cheapside. You could make a magnetic composition by the use of processes that are described in most works on chemistry.

J. B.—There is no tannin in oak wood, it is only present in the bark. There is a very small quantity of tar in the wood, but the cost of its production would exceed its intrinsic value.

T. C. (Chowbent).—Supposing that the person you allude to has really described something in his specification which has already been covered by your patent, that in itself does not constitute an infringement. Even if the machine or part of the machine patented by you were actually made for *experimental* purposes, this has been ruled, according to the case of Jones *v.* Pearce (Webster's Patent Cases, 125), to be no infringement. If, however, the party employs others to make machines according to your patent, and sells such machines, or himself makes and vends such apparatus, it is an infringement, and you can proceed against him as the law directs.

Correspondence.

◆

SUBMARINE TELEGRAPHY.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

SIR,—In my last letter, in its second paragraph, Ireland has been misprinted for Iceland, as I have little doubt would occur to all who read it.

With reference to Captain Selwyn's remarks on my proposition for surface telegraphy, it humbly seems to me that the difficulties with which he surrounds it could all be avoided. But I shall first allude to what he says about the alleged undoubted existence of *under* currents in the ocean. And I shall commence by quoting from Maury's own book a fact recorded in it extremely hostile to the truth of the existence of such *under* currents:—"In confirmation of these views as to the existence of a cushion of still water at the bottom, I bring in for farther evidence the testimony afforded by Commander Dayman, R.N., while running his line of deep sea soundings along the telegraphic plateau, in H. B. M. S. 'Cyclops.' On one occasion he hauled up from the bottom a coil of 200 fathoms of deep sea line. It had been laid at the bottom round and round in a coil, with as much regularity as it could have been coiled on deck by hand, thus showing either that there was no current there at all, or that the upper and under currents so nearly counteracted each other that the line passed perpendicularly through the still water."—Chap. 21—"The Atlantic Telegraph."

Now what do we find here? Not merely what Maury says, "a cushion of still water at the bottom," but, if I may be allowed the expression, a cushion of still water all the way from top to bottom; for his alternative about an alleged upper and under current compensating each other so exactly as to produce the result in question, is a most gratuitous, and, in the circumstances, an utterly incredible idea. But, enamoured as Maury is of his under-currents, he could not bring himself to dispense with their existence, and hence the alternative. Now the simple, clear, conclusive fact recorded by Commander Dayman ought, with all truly scientific minds, to raise the greatest doubts of, if it should not altogether abolish, the idea of under currents. And with such a significant fact against their existence, I must beg leave, with all respect, to decline adopting Captain Selwyn's assurances—which, at any rate, are far too sweeping to be relied upon—that they exist. Air, no doubt, has under currents; but water is about 800 times denser than air, and its particles have much more friction on each other, and, consequently, are vastly more sluggish and immoveable, and, therefore, in my humble opinion, the ocean can have no under currents. To reason that because air has under currents water must have them also, is utterly ridiculous, and disgraceful to the science of the nineteenth century. There is as much, or more, alliance between solid matter and water, than between air and water. And it will yet be finally established that, while the ocean resembles air in having currents on its surface, it resembles the dry land in having no currents in its depths; thus holding in its action, as it does in its nature, an intermediate position between the two. Of conrse, when a volcano breaks out at the bottom of the sea, there will be ascending currents of water. But this is a rare and restricted kind of action, and not what Maury means by under currents. Capt. Selwyn says—most inconsistently it seems to me, according to his own ideas—"the greater the depth the less disturbance probable from this cause (under currents) at or near the bottom." I beg leave to ask him most respectfully—why? I may further remark that I take up your space with less reluctance on this point because, whatever may become of my proposition, it is desirable on every account that the groundless—the unscientific—idea that under currents exist in the ocean should be eradicated, as false ideas are always hostile to improvement in some shape or other.

Captain Selwyn states other objections to surface telegraphy, involving, chiefly, the mechanical difficulties in constructing the line. These, of course, I at once admit are real difficulties, and not imaginary, like the one we have just been discussing. But they seem to me to be all easily surmountable.

He appears to think that only one ship could be employed in mooring the buoys and in laying the telegraph cable. But there could and would be two at least—one to moor the buoys, the other to lay the cable.

He seems to apprehend much danger to the telegraph cable, as far as I understand him, from its own weight. Now it is to be made of very slightly more specific gravity than sea water—enough to make it sink, and nothing more—so that it would scarcely have any weight at all.

He seems to doubt if the chains, or other means to retain the buoys in their places, would be strong enough at two miles depth to support themselves. I see no reason to doubt it, considering that there would be no foreign strain upon them.

When I said that the telegraph line would be accessible for repair, it involved that it might be under-run from buoy to buoy; and nothing the captain says impugns this, though he starts some rather intangible objection to it.

As for the experiment the captain proposes I should make, it is ingenious, but would not be conclusive as regards the ocean and a telegraph line so light as is proposed to be made; but even though it were conclusive, as to the line touching the bottom of the ocean, there would still be left a large balance of advantages in favour of my plan as regards any route, but more especially if the Northern route is adopted with all its special advantages.

I have thus (as briefly as I could with reference to your space) answered generally Captain Selwyn's objections; to whom, whatever be the result, I feel greatly obliged for the trouble he has taken or may take with my views. H. K.

Edinburgh, April 13, 1863.

ATLANTIC TELEGRAPH.

SIR,—Circumstances prevented me at the time answering "H. K.'s" invitation to criticize his scheme for laying a Telegraphic Cable to America by means of supporting buoys, &c., as contained in your number of March 27th; but, perhaps, it will be satisfactory to him to state that I perfectly agree with Captain Selwyn in the impracticability of the scheme.

I had made a few notes on "H. K.'s" letter, in which I had, for the sake of argument, dismissed the subject of currents altogether, and endeavoured to prove, from the insuperable difficulties attending the placing of the buoys in such deep water, or even in ascertaining the depth to within the number of fathoms he proposed to submerge them, it would be impracticable,—also the little effect the buoys would have in supporting 300 or 400 miles of cable, for although we have a cable sufficiently light (Duncan's Ratan) to float if necessary, still it is not probable that even that cable would remain at the same specific gravity as when laid, but from the accumulation of weed, barnacles, &c., would gradually get heavier and sink, so that the weight on the buoys would gradually increase till they would be dragged so far down that the enormous pressure would cause them to collapse; so that "H. K." like the person to whom the Dutchman proffered one hundred reasons for not firing a salute, the first being that he had no powder—the other ninety-nine were excused—must rest satisfied that, as it is impracticable to lay his buoys, no other argument need be entered into, and that "for weal or for woe" an Oceanic Telegraph Cable must lie on the bottom.

And now, Sir, allow me to examine a little into the nature of the arguments advanced as reasons why a cable should not lie on the ground, because I cannot but think they are difficulties rather imaginary than real. "H. K." has stated his arguments as being—

1. The thorough inaccessibility of the cable laid at such a depth for repair;
2. The pressure of the great superincumbent mass of water; and—
3. The utmost uncertainty as to the suitability of the bottom for the cable.

In answer:—The first is the only one tenable; and although cables have been raised from great depths and repaired, still, I believe, that to raise an oceanic one from 2,000 fathoms to be perfectly impracticable, or, if done, the cable would be so injured by the act that the remedy would prove worse than the disease.

2. There is no pressure of the superincumbent mass of water; but, like the pressure of the air on our bodies, it would be equal on all its parts, so that if a cable is well made, the great pressure to which it is subjected would tend rather to consolidate its parts than to injure it; but the effect could be easily tested by placing a portion of cable, hermetically sealed at the ends, in a hydraulic press and subjecting it to a pressure of 500 atmospheres (which would be more than equal to any pressure at the depths between this and America), and examining it afterwards. If, as is stated, by being submerged at those great depths the conductor loses in electrical conduction, it is a case for the electricians to study, and a difficulty to be overcome, for lie on the ground it must—at least, such is my humble opinion.

The third objection is the one most often quoted—viz., the suitability ofe th bottom for the cable. Strange as it may seem, I do not think it signifies what the nature of the bottom is on which an oceanic cable is to lie (I allude, particularly to the deep water—near the shore it it is of vital importance). Several Admiralty pamphlets on deep sounding (obtainable at Potter's, Poultry), will prove that a heavy weight, dragging a small line *vertically* through the water, reaches the bottom at 2,000 fathoms so slowly, that to persons on the surface it is difficult to determine the minute of contact; if such be the case, how very gently must a cable 1½ or 2 in. in circumference, reach the same depth when laid horozontally along the surface of the water and allowed to sink with its own gravity to the bottom? It is generally allowed, from the evidence of the minute and perfect formations brought to the surface from these great depths, that the water at the bottom must be in a state of perfect quiescence, therefore no abrasion from its movement need be feared; so that, considering the density or specific gravity of the water at the depth the cable must fall and lie as lightly on its bed as a feather on the surface of the earth; and even supposing the cable did not take up the inequality of the ground, but hang in a bight from one point of rock to another. My firm belief is (for the reasons stated), that it would not receive any injury as long as no attempt was made to raise it.

I do not pretend to high scientific acquirements. I merely give an opinion, and state the reasons on which I ground it. Those who feel an interest in the subject and study the question, are the best judges if they are sound. I am, however, pleased to find that some grant me the meed, denied by Dr. Wallich, viz., of writing common sense, and even endorse my opinions with their names; but Dr. W. seemed more annoyed at my preserving my incognito than anxious to support his theories or controvert my arguments against them; but if he wishes to know me personally I will tell him when and where I will introduce myself—it will be on the occasion when he propounds his next scheme before the Royal Geographical Society at Burlington House.

I am, Sir, yours, &c.,

AN OLD SAILOR.

VELOCITY OF PROJECTILES.

SIR,—Permit me to draw your attention to some apparent inaccuracies in the first article of your issue of April 3rd.

The effective force of Whitworth's projectile is stated in the 1st col. as 21.06; in the 2nd col. 22.06. Moreover, the effective forces measured as there indicated "by multiplying the weight into the square of the velocity," would not be—

Whitworth.	Armstrong.	L. Thomas.
21.06.	22.13.	22.29.

as there stated, but—

Whitworth.	Armstrong.	L. Thomas.
22.75.	21.60.	22.14,

if 1,215 ft. per second be assumed for the latter.

I annex the calculation :—

OBSERVATOR.

MACHINE BELTING.

SIR,—In your number of March 20th, speaking of Mons. Roullier's patent machine belts, made of small links of leather, united in the form of a chain by joint-pins, you say:—"It appears to us that an objection will be found in this belting from the fact that there is necessarily a tendency in the joint-pins to bend to the curve of the pulley, and a continuation of this action would naturally lead to a breakage of the joint-pins." I enclose you a sample of the belt, by which you will see that as the pins lie across the pulley at right angles with the length of the belt, it is impossible that they can bend—indeed, so far from being liable to this objection, I have these bands superior to the ordinary kinds (on account of their perfect pliability) for places where it is necessary to use both surfaces. Even if the faces of the pulleys are made slightly convex, this objection would not hold good, as the spring of half an inch for a piece of wire a foot in length (which is the proportion in which the rims are curved) would not tend to damage it at all. I have seen specimens in Paris which have been in constant use for twelve months, and are not at all affected.

As I am the sole licensee and manufacturer of these belts for this kingdom, and as any deprecatory remarks of yours, owing to the widely-spread circulation of your MAGAZINE, are calculated materially to injure me, I trust to your sense of justice to insert these few lines in your valuable journal.

I am Sir,
Your obedient servant,
W. T. ROWLETT.

Leicester, April 13, 1863.

PATENT LAW REFORM.

SIR,—The question of "Patent Law Reform" admits, I think, of a few additional observations before I lay my scheme before your readers. Some topics yet remain, which may, as it seems to me, be advantageously noticed before we come to a scheme. The report of the Commissioners is now, I believe, speedily expected; but it is doubtful whether any measure will be matured this Session. The subject is one which certainly requires care and consideration on the part of the Legislature. A hasty and inconsiderate reform will only add to existing difficulties.

This letter I devote to the consideration of the two following points, viz.:—

1. The present duration of a patent
2. The necessity for a preliminary investigation.

1. *The present duration of a patent.*—This, no doubt, is a serious consideration to our inventors. Some, I believe, think that the difference between a patent and copyright is unjustifiable. Though it may be somewhat difficult to answer this question, the analogy is not, I think, identical. A letter like the present does not obviously admit of a lengthened discussion of such a topic. The report of "The Inventors' Institute," deals, I think, ably with this subject. On the whole, it is, I think, worth consideration, whether the duration of a patent might not judiciously be extended. However, the present powers of extension must not be overlooked. If the present period should be extended—say to 21 years—such period should, I suggest, be absolute, and the powers of extension be taken away. On the whole, I doubt whether the present regulations can substantially be improved.

2. *The necessity for a preliminary investigation.*—This is certainly a branch of the subject that requires the Commissioners' serious attention. The interests of the inventors and the public are obviously involved in this question. At times I have thought, as I candidly acknowledge, a preliminary investigation desirable. Much, no doubt, can be urged on both sides, but it is difficult to "balance the scales." It must be admitted, I apprehend, that patents for very trifling inventions are frequently taken out. In some instances, these inventions consist of little better than what are known as "mechanical equivalents." My impression is, on the whole, that this is one of many subjects for which it is impossible to legislate satisfactorily. The ideas which spring up in a man's mand are frequently traceable to a *chinic origin*, and are what we may call "instinctive ideas." These are commonly adapted to the peculiarities of an age for which Providence is making special provision. Great danger would, I feel, attend the suppression of such ideas, however occasionally desirable to check ridiculous patents.

These views, Sir, I submit to your readers, but with deference and respect. The Commissioners would, as I suggest, receive much assistance if there was a larger expression of public opinion. Allow me to press this on the attention of your readers.

I am, Sir,
Yours very obediently,
J. CULVERHOUSE.

3, Compton-street, Ball's-pond,
April 15, 1863.

REVOLVING CUPOLAS.

SIR,—I do not pretend to know anything about iron ships, but I cannot see why the revolving cupolas should not be made square or (better still) triangular, with the port or ports at the corners. I presume that the guns would be pointed at the enemy, in which case shot could only strike it at an angle, unless, indeed, by good luck they struck the knife edge, and that would be by far the strongest part of the cupola.

Whether this suggestion is of any value I leave to you.

Believe me, Sir, yours sincerely,
Woodbine-cottage, Sidmouth, C. C.
April 15, 1863.

FOG SIGNALS.

SIR,—With reference to your article, "Fog and Fog Signals," April 3rd, 1863, I would suggest that there would be little difficulty in constructing buoys with self-acting whistles, on the principle for which my father took out a patent sometime between 1830 and 1832—namely, by loose floats hinged on to] the buoy, and working an iron rod lever, which might either press on an elastic, so as to sound a whistle with every motion of the waves, or to accumulate air in a reservoir till it had attained sufficient force to overcome a loaded valve, and thus give out a louder sound, not much inferior to a whistle sounded by the escape of steam.

I am sir, your obedient servant,
CHAS. BATHOE.

28, York-place, Portman-square,
11th April, 1863.

SIR,—Having noticed your observation on the comparison made between the "Stethoscope and the Steam Engine Indicator," in your review of Mr. Hopkinson's work, it may not be amiss to remark that Mr. D. K. Clark made the same comparison in his introductory preface to "Railway Machinery," in 1855. Referring to the application of the indicator to locomotives, he described that instrument "as a sort of stethoscope for testing their physiological condition." A. B.

London, April 11, 1863.

MECHANICAL MOTIONS.

SIR,—In your review of my work on Mechanical Motions, you state that the Sun-and-planet and Whitworth's variable motions are not described. The former is described in plate 5, fig. 16; the latter, plate 8, fig. 18.

Mr. Whitworth's name is not mentioned in my description, because his invention was (I believe) the application of the motion to planing machines.

Referring to your concluding remarks, you will find on closer examination that the number of well-known motions forgotten or left out, to be far exceeded in number by those described therein for the first time, which I think is of greater importance. I am, &c.,
JOSEPH WILLCOCK.

Meetings for the Week.

MON.—*British Architects.*—At 8 p.m.
United Ssrvice Inst.—"On Steering and Manœuvring Ships with Broadside Batteries by Twin Screw Propellers," by Com. T. E. Symonds, R.N., at 3.30 p.m.
Medical.—At 8.30 p.m.
TUES.—*Inst. Civil Engineers.*—I. Discussion upon Mr. Brunton's Paper "On the Scinde Railway." II. "Account of the Coffer-dam, the Syphons, and other Works constructed in consequence of the Failure of the St. Germain's Sluice of the Middle Level Drainage," by Mr. Hawkshaw, at 8 p.m.
Royal Inst.—"On Animal Mechanics," by Prof. Marshall, at 3 p.m.
WED.—*Soc. of Arts.*—"On the Construction of Twin-screw Steam-ships," by Capt. T. E. Symonds, at 8 p.m.
THURS.—*Royal Inst.*—"On Geology," by Prof. Ansted, at 3 p.m.
Antiquaries.—At 8.30 p.m.
Civil and Mechanical Engineers.—"On Marine Surveying," by Messrs. F. E. Cooper and G. J. C. Dawson, at 7.30 p.m.
Royal Soc.—At 8.30 p.m.
FRI.—*London Inst.*—"Economic Botany," by R. Bentley, Esq., at 7 p.m.
Royal Inst.—"On Luminous Meteors," by Alex. S. Herschel, at 8 p.m.
United Service Inst.—"On the Progress of Military Science during the Year 1862," by G. R. Burnell, Esq., at 3 p.m.
Architectural Assoc.—Class of Design—Dairy.
SAT.—*Royal Inst.*—"On the Science of Language," by Prof. Max Müller, at 3 p.m.

Miscellanea.

The total number of workmen now employed upon the "Royal Sovereign" turret-ship at Portsmouth is nearly 300, additional hands, we are glad to observe, having been placed upon her within the last few days. Her plating is now being carried on rapidly, and the cylinder or hollow pivot of her foremost turntable and turret is in its place.

A gang of upwards of 80 convicts are now employed in No. 10 dock at Portsmouth, in chipping off with scrapers the composition and rust from the two lower tiers of armour-plates on the sides of the "Black Prince" iron frigate. The oxidation on the surface of the plates amidships has been considerable in the wash of the water-line, as must naturally be the case with slabs of iron only protected by paint or patent compositions.

Mr. Arthur Gearing will deliver a lecture on a new system of artillery adapted to the modern requirements of the Navy, at the United Service Institution, on the 20th inst., at half-past 6 o'clock p.m. The object appears to be, to first establish the expediency of determining the characteristics of the gun best suited to the Navy under the altered conditions of modern warfare. It being conceded that the "fleet of the future" can only be accurately determined by the ascertained practicability of the "guns of the future," consequently *relative* ultimate economy and efficiency are involved in this vital consideration of the subject.

Mr. James Bruce writes to us to say that he has discovered a new fibre, which, for "stuffing beds," has been pronounced by the leading firms of manufacturers and upholsterers, &c. (to whom it has been submitted), as superior to cotton, wool, flock, prepared rags, velvet cuttings, &c., for the above purpose. It is of the most delicate texture, not liable at any time to knot or decay, free from smell and dust, and, moreover, very abundant and cheap.

The Americans have discovered a new method of loading their rifles and guns, which has two advantages—that of economizing time and saving money. The bullet and ball have the powder ready adhering to them, and over that is laid a thin layer of gum, keeping it compact and dry; thus neither cartridges nor paper are necessary, and only half the usual time for loading required. It is said to have answered so well that the French Government think of adopting the method.

An American has invented a lock umbrella stand. The moment the umbrella drops to its place in the rack the handle is by a single movement grasped and held firmly in the clutch of a lock which nothing but the key specially manufactured for the particular depository can loose. The key, which is practically a pawn ticket for the article, is of less weight and no greater size than a nickel cent, and adds no perceptible weight to the vest-pocket. The invention is at once ingenious and useful. Its introduction into counting rooms, hotels, offices, and halls, and other places of public and private resort, must become general.

The Admiralty have entered into a contract with Messrs. Campbell and Johnston for the erection of a new crisson at the entrance to the second dock at Chatham, in which the iron frigate "Achilles" is under construction. The cost of the new caisson is estimated at £3,500. Directions have likewise been received at Chatham for the erection of a new boiler-house at the "Achilles'" workshop for the reception of the new machinery which is ordered to be purchased and erected during the present year. Among the sums voted for the expenses at Chatham dockyard during the current year is one of £16,480 for wages for 480 additional hired mechanics and artizans to complete the work already in progress at that establishment.

During the month of March two hundred gold, silver, and copper mining companies were formed in San Francisco to develop the mines in California, Nevada, and North Western Mexico; their nominal capital was over eighty millions of dollars.

Austrian Gun Cotton.—Take cotton yarn and twist it into strands of suitable size to answer the same purpose as grains in gunpowder. (The size of these strands can only be ascertained by experiments.) It is then steeped for a few minutes in nitric acid contained in a stoneware vessel, squeezed, and thoroughly washed by water, which is permitted to fall upon it from a pipe set at a height of several feet. After this it is squeezed, and dried in a room heated to 130 deg. Fahr., when it is ready to be treated with a mixture of nitric acid of 1·52 specific gravity, and sulphuric acid of 1.14 specific gravity. These acids, in equal quantities, are mixed together in a glass or stoneware vessel, and allowed to stand for twenty-four hours, then the prepared yarn is immersed in it for forty-eight hours, with occasional stirring; the vessels being covered; then it is squeezed, washed for several hours in running water, and dried again. After this it is soaked for a short period in dilute silicate of potash, squeezed, washed again, dried, and is fit for use. This gun cotton is manufactured by M. Reny, of Vienna. It emits but little smoke, and is not subject, like common gun cotton, to explode by percussion.

Sketch of the Iron-clad "Chillicothe."—The iron-clad "Chillicothe," whose brilliant exploits on the Yazoo river have rendered her name familiar to our readers, was built at New Albany. She is 170 ft. in length, 60 ft. beam, and 7 ft. deep, and draws, when loaded, about 6 ft. of water. She has four boilers, high pressure of course. She was built for a thirteen knot boat, and has realized her builders' most sanguine expectations. She is completely mailed with 1 and 2-inch iron, and the turret, which is stationary, with sloping sides and shell-proof gratings overhead, is clad with a double wrought-iron plating, 3 in. in thickness, backed by solid oak 16 in. thick. Her armament is two 11-inch Dahlgren guns in the turret, and four 24-pounder howitzers in broadside. She has a house extending from the turret to the wheels, which is occupied as quarters for the captain and officers when not in action. There is also a full complement of rooms below. Her engine, boilers, and lower quarters are all protected by mailing. She has appliances for throwing hot water, in event of being boarded by the enemy. She has two immense and powerful capstans, to heave her over shoals and bars in the rivers where there is low water. She has been in commission only a short time, and her superior build and powers of resistance gave her the place of "head boat" in the expedition in which she now performs so gallant and bold a part.

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

The Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

Steam Engines, &c., 2538, 2545, 2572.

Boilers and Furnaces, 2570, 2583, 2584.

Roads and Vehicles, including railway plant and carriages, saddlery and harness, &c., 2541, 2573, 2596, 2599, 2602.

Ships and Boats, including their fittings, 2561.

Cultivation of the Soil, including agricultural implements and machines, 2563, 2589.

Food and Beverages, including apparatus for preparing food for men and animals, 2543, 2594.

Fibrous Fabrics, including machinery for treating fibres, pulp, paper, &c., 2547, 2558, 2559, 2564, 2568, 2575, 2585, 2592, 2593, 2595, 2600, 2601, 2607, 2608, 2610.

Buildings and Building Materials, 2540, 2548, 2562, 2577.

Lighting, Heating, and Ventilating, 2537, 2542, 2553, 2554, 2555, 2560, 2566, 2567, 2571. 2597.

Furniture and Apparel, including household utensils, time-keepers, jewellery, musical instruments, &c., 2537, 2546, 2549, 2551, 2557, 2576, 2578, 2586, 2587, 2590, 2606, 2609.

Metals, including apparatus for their manufacture, 2569.

Chemistry and Photography, 2552, 2556, 2565, 2579, 2598, 2605.

Electrical Apparatus, 2574, 2591.

Warfare, 2544.

Letter-Press Printing, 2582.

Miscellaneous, 2493, 2550, 2580, 2581, 2603, 2604.

2537. J. Whines. *Improved machinery for filling dipping clamps with tapers and match splints.* Dated September 16, 1862.

The object of this invention is to facilitate the separation of tapers or match splints, of whatever form or material they may be made. On one side of the machine is a box or hopper with a series of divisions into which the tapers or splints are placed; at the bottom of this box or hopper is a slide with a series of grooves at one end running across at right angles. When the grooved portion of the slide is drawn under the box or hopper containing the tapers or splints, the grooves become charged therewith. At one end of the box or hopper, and immediately over the slide, is a toothed roller with recesses or grooves at intervals, into which is fitted a fender or check; by imparting with any suitable gearing rotary motion to the roller, that portion of the side charged with the splints or tapers is readily withdrawn from the box or hopper into a tube with guideways or grooves corresponding with the grooves in in the slide; the splints or tapers are now thrust out of the grooves in the slide, and through guideways into the dipping clamp, by a series of plungers connected to a reciprocating bar put in motion by a rocking shaft with levers and connecting links; to this bar are also secured two or more taper pointed rods, which may be either round or square, and which separate the boards to receive the splints or tapers between them, and cause the frame and boards to descend; the taper pointed rods are then withdrawn, and the boards which were on the upper side of them fall on to the row of splints or tapers just deposited on the lower board, and are kept from contact with each other by vertical guides. In front of the dipping frame is a guard to prevent the splints or tapers from being thrust farther than is necessary; this guard is provided with a moveable panel, which, after the frame is filled, is forced by eccentric rollers against the ends of the splints or tapers to put those which have been driven too far back again, after which two slips are withdrawn from between the dipping frame and the front of the machine, and the frame itself is forced by levers close to the front of the machine, thereby putting the ends of the whole of the splints in one plane. They are then screwed fast together, and the frame charged with the splints or tapers is removed for dipping in the igniting composition. *Patent completed.*

2538. B. F. Weatherdon. *A new or improved engine for obtaining and applying motive power.* Dated September 16, 1862.

This invention has reference to a new or improved construction of engine to be worked by volatile chemical agents, or similar fluids, capable of being readily converted into vapour and condensed by ordinary means at temperatures below the boiling point of water, by which great economy in the power, as also in the construction and wear and tear of the engine, is obtained, and consists in the cylinders and working parts of the engine being wholly enclosed, and caused to work within the boiler and generator, in such manner as to communicate direct rotary motion thereto, through the medium of a fixed shaft or axis, whereby all danger from leakage, loss of power, or otherwise, is obviated, and a more simple and compact form and construction of engine obtained than at present, toothed rack and segment wheels in some cases being employed in preference to the crank, together with steam or hot water jackets surrounding the boiler, either separately fixed, or made to revolve in in connection therewith, as also with condensers in like manner. *Patent abandoned.*

2539. J. G. Bunting. *A mechanical horsebreak.* Dated September 16, 1862.

In carrying out this invention, the inventor proposes to construct a horizontal framing somewhat in the form of a pair of cart shafts, the hinder extremities of which are left open for the entrance of the horse. These shafts are connected by means of an arched axle, the arch extending over and across the haunches of the horse, ordinary carriage or cart wheels being attached to the arms of the axle. The fore parts of the shaft rest on a fore carriage and wheels, to which is attached a pole or shafts for the purpose of harnessing either a single horse or pair. The object of this invention is, that an ungovernable horse may be harnessed within the frame or carriage, and be retained therein by means of bands and straps passing over his back and under his belly, and attached to each side of the frame or carriage, by which means he can neither lie down nor rise from the ground, harness being attached to the fore part of the framing, and also a collar strap, whereby the horse is securely held in position and compelled to follow the leader or leaders in the pole or shaft. *Patent abandoned.*

2540. G. L. Lee. *Improvements in the manufacture of shutters for shop fronts, doors, and windows.* Dated September 16, 1862.

In carrying out this invention, the patentee proposes to construct shutters of sheet metal, either plain, corrugated, fluted, or zigzag, in divisions or sections of any desired width, the edges thereof being turned over and doubled for strength, and also, if required, for the purpose of forming a rabbet joint to same. The shop front or window is to be provided with a groove or bar at the top and bottom thereof, and running the entire length of the window or front, so as to form a groove or rabbet into which the shutters are placed; likewise an upright groove or bar to receive the edge of the first shutter where occasion requires. *Patent completed.*

2541. S. Flexen. *Improvements in apparatus for ventilating railway and other carriages.* Dated September 16, 1862.

This apparatus consists in a combination of lines, pulleys, rods, weights, and eyes so fixed in relation to each other that, by moving the windows or lights, shutters, blinds, or otherwise, they then open or close the ventilator simultaneously, or regulate either to any required height or space, as described. *Patent completed.*

2542. W. Clark. *Improvements in the treatment of peat and peat tar for the production or manufacture of various products, and in apparatus for the same.* (A communication.) Dated September 16, 1862.

This consists in obtaining subproducts, ordinarily produced from coal tar, from peat tar, which is also termed azoted tar, or, in other words, the manufacture or transformation of the said tar into the subproducts below enumerated—viz., benzine, for cleaning purposes, or that used for the manufacture of nitro-benzine; petroleum and naphtha, for lighting purposes; phenic acid and its azoted derivatives; creosote; methylated alcohol; and various other products. *Patent completed.*

2543. R. Moreland, jun. *Improvements in machinery for preparing and cutting hops.* Dated September 16, 1862.

This consists essentially in the use of two rotating frames, one revolving within the other, each frame being provided with bars so arranged as to act as cutters. *Patent completed.*

2544. R. Lakin. *Improvements in the mode of plating or shielding ships of war.* Dated September 16, 1862.

This consists—1, in applying springs between the plates or shields and the sides of the ship, to act as an elastic cushion to the plates; 2, in supporting the plates, or brackets, or the like attached to the sides of ships, instead of bolting the plates to the sides; 3, in applying to the sides of ships metal pipes or tubes, or metal bars made wholly or partially of a circular or other curvilinear form. *Patent abandoned.*

2545. H. Jordan. *Improvements in rotary engines.* Dated September 16, 1862.

This consists in placing within the steam cylinder employed another cylinder or enlargement of the shaft, which latter is of less diameter than the steam cylinder. Two sliding pistons are arranged to work independently of each other in connection with this inner cylinder, and the ports are so arranged that one of the pistons may for a time be pressed in by the full pressure of steam from the boiler, whilst the other piston is being acted on by steam expansively. *Patent abandoned.*

2546. C. E. Guye. *Improvements in apparatus for cutting and finishing the teeth of watch wheels.* Dated September 16, 1862.

We cannot here give space to the details of this invention. *Patent abandoned.*

2547. L. Leigh. *Improvements in certain machinery for stretching and glossing silk, wool, and other fibrous materials.* Dated September 17, 1862.

This relates to a previous patent of the year 1860 (No. 1613), and consists in giving a revolving motion to the hanks during the process of stretching and glossing. Where the hanks do not require steaming, the patentee substitutes for the steaming-box a suitable frame, with hooks and other apparatus for holding and, when necessary, revolving the hanks while being stretched. *Patent completed.*

2548. S. Le Keeler. *Improvements tn veneer-cutting machinery.* (A communication.) Dated September 17, 1862.

This consists in suspending the table or currier to which the log is attached by screw bolts from two points, which enter and turn freely in the table, and which are inserted in discs or arms attached to the ends of rotary shafts. A rotary motion in opposite directions to each other is imparted to the shafts by a pinion secured to an arbour, which gears into two large cog wheels attached to the shafts, whereby the table receives a compound motion around the centres of the shafts, and in a direction parallel to a line drawn through the said centres. By this motion the cog is brought in contact with the knife at every revolution of the arms or discs, and that by a rotary drawing motion or stroke, whereby the perfection of the cutting operation is secured. The knife is secured to the frame that forms the bearings for the shafts, and arranged with a self-acting feed moving it the thickness of the veneer to be cut towards the log at the moment the log is at its highest elevation. *Patent abandoned.*

2549. R. Cranston. *An improved washing machine, to be called "The Waverley Hotel Washing Machine."* Dated September 17, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2550. J. Simpson. *An improved composition for coating or covering moulded or other surfaces, and in apparatus for applying the same thereto.* Dated September 17, 1862.

This composition is formed of an amalgamation of whiting, china clay, and glue, in such proportions as to form a semi-fluid mixture about the consistency of cream, or slightly thicker. The apparatus for applying this composition consists of a series of templates or gauges screwed together at the ends in a vertical position in a box form, the top being open for the reception of the composition. *Patent completed.*

2551. W. E. Newton. *Improvements in watches or time-keepers.* (A communication.) Dated September 17, 1862.

This relates to keyless watches, and more particularly to that part of the gearing whereby the hands are moved over the face of the watch. The object of this invention is to remedy various well known defects by the interposition of an intermediate wheel mounted upon a rocking frame, which is brought into action when the hands are required to be set. *Patent completed.*

2552. W. and W. H. Watson. *An improved process or processes for the preparation of certain colouring matters from aniline.* Dated September 17, 1862.

Here the inventors mix aniline with aqua regia in the proportion of about two parts of aniline and one part of aqua regia, and subject the mixture to a temperature of about 340 deg. Fahr., and by continuing this temperature colouring matter is gradually formed. The colouring matters produced are red, and blue, and another substance of a dark colour. They wash out the red colouring matter by water, and then treat the residue with alcohol, which dissolves the blue colour and the dark substance. To the alcoholic solution they add five or six times the volume of benzole, and leave the mixture at rest for some time to settle. The benzole retains in solution the black colouring matter, and the blue is precipitated. They then decant off the liquids. This blue colouring matter is soluble in alcohol, and is then ready for use. *Patent completed.*

2553. J. Douglas. *Improvements in apparatus applicable to close fire ranges, usually termed kitcheners, for the purposes of ventilation.* Dated September 17, 1862.

Here the patentee places the register or plate about two feet above the breast of the chimney, so as to form an inclined space of the expanded mouth of the chimney, which is, however, open below, and extends over the area of the range. From this plate he continues a tube up the chimney, which carries off the effluvia from the cooking, and ventilates the kitchen. A communication into the ventilating tube is also made near the ceiling. Rooms above the kitchen may be ventilated by lengthening the tube and providing suitable communications. *Patent completed.*

2554. G. Haseltine. *Improvements in apparatus for the manufacture of gas from petroleum oil and water, or from cannel coals, bituminous coals, schists, tar, crude coal oil, or other hydro-carbons and water.* (A communication.) Dated September 17, 1862.

This relates chiefly to the construction of a compound retort, to be used vertically or horizontally, containing three chambers, so as to admit of the introduction of water in its spheroidal state into the chamber at the bottom of the retort at a very high temperature, simultaneously with intensely hydro-carbon gases and vapours for the formation of permanent illuminating gases, and the prevention of subsequent condensation of volatile hydro-carbons, or the decomposition of carbon in the different parts of the apparatus. *Patent abandoned.*

2555. J. H. Johnson. *Improvements in gas burners.* (A communication.) Dated September 17, 1862.

This consists in rendering a gas burner self-acting, by so disposing a spring valve as to shut off the gas when closed, and allow of a free passage of the gas through the burner when opened. The opening and closing of this valve is effected by a bar composed of two metals soldered together and having different rates of expansion and contraction. *Patent completed.*

2556. L. Mond. *Improvements in obtaining hypo-nitric acid and nitric acid from nitrate of soda.* Dated September 18, 1862.

Here the nitrate of soda is to be made with a substance of basic or of indifferent character, which is neither melted nor changed by treating it with the nitrate of soda to redness. The following substances are some of those preferred:—The peroxide and the magnetic oxide of iron, the sesqui-proto-oxide of manganese, which is always obtained by heating any other oxide of manganese to redness, the oxide of copper, the sesqui-proto-oxide of cobalt, and the proto-oxide of nickel. This mixture of the nitrate of soda with one of the above-named substances is then to be heated in common retorts to redness. By this process a gaseous mixture is obtained composed of hypo-nitric acid, oxygen, and nitrogen, which can be immediately used for the manufacture of sulphuric acid. To obtain nitric acid from this mixture of gases, it must be conducted over cold water contained in suitable vessels. The residue in the retorts may be advantageously employed for the manufacture of caustic soda. *Patent abandoned.*

2557. P. H. Whitehead. *An improved support or stand for casks, barrels, or other similar vessels.* Dated September 18, 1862.

This improved cask-stand is supported upon a horizontal shaft, having bearings in two side standards, and the frame is brought to a vertical position to receive the barrel by turning a handle in connection with bevel gearing, and a worm and worm quadrant on the horizontal shaft, and by reversing the handle the cask is brought to a horizontal position, and may be tilted by the same means. *Patent completed.*

2558. R. Kay. *Certain improvements in printing calico and other surfaces, and in apparatus connected therewith.* Dated September 18, 1862.

This relates to the sieve used by block printers to supply the colouring matter, and consists in adapting such apparatus to cylinder printing particularly. The improved sieve consists of an internal cylinder, having an extended covering of india rubber, so as to form a chamber between the two, which chamber is to be supplied by tubes with water or liquid from a cistern, and the pressure duly regulated by valves; the surface of the india rubber may either be corrugated or covered with woollen or other fabric. The invention consists also in the use of an endless band of wire gauze as a substitute for the band of felt for supplying the colouring roller with colour by transferring it from the furnishing roller rotating in the colour trough to the said colour roller. *Patent abandoned.*

2559. W. and J. Todd. *Improvements in machinery or apparatus for "collecting waste or fly" from spinning machinery, whether for cotton or any other fibrous material.* Dated September 18, 1862.

This consists in the use of a series of rollers caused to revolve by traversing over the places where the waste or fly accumulates, so that in their progress they shall collect all waste or fly and retain it upon their surfaces until stripped. *Patent completed.*

2560. W. H. Browne and H. Armstrong. *Improvements in dry and wet gas meters.* Dated September 18, 1862.

This invention was described and illustrated at page 233, No. 222 of this journal. *Patent completed.*

2561. G. S. Moore. *Improvements in shipbuilding.* Dated September 18, 1862.

Here the inventor prevents the copper fastening from coming in contact either with the angle iron or with the bilge water (in ships built with an iron frame and wood planking) by surrounding its upper end with another metal which has not the same prejudicial action on the iron. He also makes the ends of two planks where they meet to lap the one over the other for a distance somewhat exceeding the space between the ribs, and he scurfs the ends together. The joints each fall correctly over two of the ribs, and the ends of each plank are fastened to each of the ribs, by preference, with fastenings as before described. *Patent abandoned.*

2562. J. W. Woodford. *Improvements in machinery and apparatus used for driving and drawing piles, also for raising soil, and also in shoes and hoops for piles.* Dated September 18, 1862.

We cannot here devote space to the voluminous details of this invention. *Patent completed.*

2563. T. Watts. *Improvements in combined thrashing machines.* Dated September 19, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2564. G. Loury. *Certain improvements in machinery for preparing, cleaning, cutting, and shortening the lengths of tow and other fibrous materials.* Dated September 19, 1862.

Provisional protection has not been granted for this invention.

2565. W. Glass. *Improvements in the treatment of sulphuret of antimony, and in obtaining products therefrom.* Dated September 19, 1862.

This invention consists in heating to redness in a close vessel, such as a crucible, retort, or flattened dish, sulphuret of antimony (antimony ore or crude antimony), with or without additional sulphur or antimony, and projecting upon or into them or it in a melted or fluid state, by means of a fan or pump, or by other means, either from the top or from any other direction, atmospheric air or oxygen gas, or both, provision being made in the crucible or other vessel for the ingress of air, oxygen, or both, and for the egress of vaporized products of combustion, oxides and sulphoxides of antimony and sulphurous acid, which are conducted into tubes, flues, or chambers where the oxides of antimony are deposited in fine powder, and the sulphurous acid gas may be collected or used as such: or it may be converted by oxygen and steam (aqueous vapour) into sulphuric acid, as is usually practised in vitriol works, or otherwise treated, while a portion of impure metallic antimony remains in the vessel after the operation has been continued some time, and may be purified for metallic antimony of commerce, or refined for gold, silver, or other metals. *Patent completed.*

2566. E. de la Bastida. *An improved cover for chimneys, adapted to prevent them from smoking, and to facilitate the extinguishing of fires therein.* (A communication.) Dated September 19, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2567. W. Tytherleigh. *An improved heater for ironing or pressing.* Dated September 19, 1862.

This invention consists of a hollow heater made of wrought or cast iron, which may also be made of brass, or of any material capable of standing heat. In the interior is fixed a burner, with holes therein to admit of one or more jets of gas, and to which is attached a tube, either elastic or otherwise, which may, if necessary, be jointed, and have a stop-cock for regulating the supply of gas to the burner. When necessary, the inventor uses with such heater a moveable board or platform for the heater to work on. *Patent abandoned.*

2568. J. and W. Smith. *An improved combination of machinery or apparatus for doubling, measuring, and plaiting woven fabrics.* Dated September 19, 1862.

The fabric is, according to this invention, doubled by passing it between the prongs of a fork, and over a rod carrying a roller, which revolves against the middle of the fabric as it moves onwards. The fabric then passes in contact with a measuring roller, and is drawn and led by other rollers to a vibrating frame, through which it is passed in order to plait it. The shaft of the measuring roller gives motion by toothed and worm gearing to an index plate, so that the quantity of fabric passed through the machine may be measured with exactness. *Patent abandoned.*

2569. J. Bouvet. *An improved mode of closing or sealing tin preserve boxes.* Dated September 19, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2570. D. C. Bridge and J. Dyson. *Improvements in the formation of boilers to be employed for warming buildings and similar purposes.* Dated September 19, 1862.

This invention consists in a new arrangement of water spaces and tubes, whereby a much larger amount of surface is exposed to the action of the heat than heretofore, and in some of the forms of boilers the smoke is also consumed, thus effecting economy in fuel. *Patent completed.*

2571. J. B. Giertz. *Improvements in gas burners or jets.* Dated September 19, 1862.

This invention relates more particularly to gas burners or jets known in the trade as "bat-wing" and "fish-tail" burners, and consists in adapting thereto a cap or cover of metal of the following construction; that is to say, the patentee forms a cap or cover of a dome shape, with a thin flat piece of metal across the centre thereof, and projecting from the outside thereof about three-eighths of an inch, leaving a slit or long opening across the cap close to each side of the aforesaid flat piece of metal, for the escape of gas from the ordinary gas burner or jet, over which the cap is placed and fits tightly round, leaving a space between and around the inside of the cap and the outside of the gas burner or jet for the gas to enter and pass through to form the flame of the burner. The effect of this arrangement is to obtain a large surface of flame with a small quantity of gas, and thus to effect a considerable saving in the consumption of gas. *Patent completed.*

2572. F. Savage. *Improvements in traction engines.* Dated September 19, 1862.

In carrying traction engines it is desirable that the driving wheels should be capable of being separately thrown in and out of gear with the crank shaft of the steam engine, so that the machine may be able to turn readily. The clutches now commonly used for this purpose are so formed that they cannot be thrown out without shutting off the steam and stopping the engine. According to this invention, the inventor forms, in the following manner, the clutches through which the driving wheels are actuated:—He makes the teeth of the clutch which engage the one with the other inclined at their sides in place of straight, as is usual, so that the incline of the teeth may give the clutch a slight tendency to come out of gear. He also makes the teeth of the clutch much more numerous than is usual for an ordinary traction engine. He commonly employs about sixteen teeth, whereas the ordinary clutch has but two or three. He finds that it is best not to form the teeth of the two clutch-plates exactly in the same manner, but that the teeth on one of the plates should be (although inclined) flat both at their sides and ends, whilst the teeth of the other plate are curved or convex on their sides. From this construction it results that, although the clutch-plates have but a very slight tendency to separate when they are held in close contact, as soon as the plates are slightly separated this tendency is increased. This construction also allows the clutch to be readily thrown in when the engine is running. *Patent abandoned.*

2573. W. M. Cochrane. *Improvements in securing the bolts and nuts of railway fish-plates.* Dated September 19, 1862.

The bolts and nuts by which the fishing-plate of railway rails are fixed are found constantly to shake loose in consequence of the vibration caused by passing trains, and men are now constantly employed to screw up these nuts. Now, according to this invention, the inventor, by preference, makes the bolt holes in the fish-plates circular, and at the outer side of the fish-plate he makes a notch or notches in the side of each hole. Between the fish-plate and the nut, and between the fish-plate and the head of the bolt, he places a washer or thin plate of such a size as to extend beyond the nut or head. This washer or thin plate has, by preference, a projection or projections on its inner side, which enter the notch or notches formed at the edge of the bolt-hole in the fish-plate; or he otherwise arranges these parts so that the washer, when pressed against the fish-plate, shall not be at liberty to turn on the bolt. The nut of the bolt is then screwed home, the washer or thin plate applied under the head of the bolt, and under the nut is bent at its edge, so that the bent parts may come respectively against the sides of the head and nut, by which both the head and the nut will be prevented turning. *Patent abandoned.*

2574. J. Imray. *Improvements in apparatus for telegraphing and signalling by means of electricity.* (A communication.) Dated September 19, 1862.

These improvements apply, in the first place, to apparatus for actuating the distance signals of railways, and for securing their correct action by means of electricity. For this purpose, on the column of the distance signal the patentee mounts a vane, disc, arm, or coloured light, which, when it is turned in one direction, shall indicate that the line is clear, and when turned partly round into another position, shall indicate that the line is stopped, or that it is unsafe for a train to proceed further. The inventor arranges in the column suitable clockwork of ordinary construction to act by a spring or weight, and he keeps the same constantly wound up and ready to turn the vane or light when a detent is withdrawn. This detent is acted on by electro-magnetic apparatus, connected by conducting wires with the station or place from which the signal is to be worked, so that an operator, by moving a suitable handle, when he desires to stop a train, introduces a battery into the circuit, which actuates the electro-magnetic apparatus, and causes the detent to be withdrawn. In combination with this arrangement, there are placed at the station, or elsewhere, bells, also connected with electro-magnetic apparatus and the conducting wires, so that when the battery is put in connection with the signal current, the bells commence to ring, and continue to do so until the distance signal has moved to its new position, when they cease to sound, in consequence of the electric current being cut off from the magneto-electric apparatus of the bells by the change of position of the vane of the distance signal breaking with the wire that communicates with the bell apparatus. He also arranges miniature vanes at the station or place where the operator is situated, which, by the action that stops the ringing of the bells, are caused to turn to a position corresponding to that of the distance signal they represent, so as to show that it has obeyed. *Patent completed.*

2575. R. R. Jackson and J. Coupe. *Improvements in looms for weaving.* Dated September 19, 1862.

The objects of this invention are—to save power, to diminish the friction and strain upon the warp, and enable the loom to be worked advantageously at a higher velocity, and all these objects are gained by shortening conjointly the "sweep" or radius of the crank and the length of the slay sword, or radius in which the slay oscillates, so as to reduce the oscillation of the slay to considerably less extent than at present in use. *Patent completed.*

2576. C. Chinnock. *Improvements in the construction of corkscrews.* Dated September 19, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2577. G. Maw. *Improvements in the manufacture of tesseræ and other mosaic inlays.* Dated September 19, 1862.

This invention consists in producing tesseræ and other forms employed in mosaic work of glass, enamel, or other vitreous material, by casting or moulding such forms upon a principle in which the finished article is discharged from a different part of the die or mould to that by which the molten material is admitted. *Patent completed.*

2578. E. Feis. *Improvements in the construction of locks, catches, or fastenings for purses, bags, or other receptacles.* (A communication.) Dated September 19, 1862.

For these purposes one of the sides of the frame of a purse, portmonnaie, bag, or other similar receptacle, is furnished with a fixed projection suitably formed for being suitably held or retained by a spring catch fixed on the opposite side or frame of the receptacle, which also carries the sliding piece, having a knob or projection passing through a slot in the frame to the outside of the receptacle. By imparting movement to this knob or projection on the outside of the bag or receptacle, an incline or receptacle on the sliding piece acts on the spring catch, so as to release the fixed projection on the opposite side, and thus allow the parts to open or separate. *Patent abandoned.*

2579. P. L. Forestier. *Improvements in photographic albums.* Dated September 20, 1862.

The patentee claims the manufacture of photographic albums in which the cartes or portrait are surrounded by a bevel-edged border, having the appearance of a frame, in any suitable manner. *Patent completed.*

2580. H. R. Fanshawe. *Improvements in the mode and means used in fishing in seas, rivers, and other waters.* Dated September 20, 1862.

This invention consists in the employment of a submerged or subaqueous light for the purpose of alluring or decoying fish, and thereby facilitating their capture. The light employed is derived from electricity, or from the ignition of oil or gas; or the patentee may employ phosphorized oil, or other luminous fluid, or any means for producing or maintaining a light under or below the surface of the water. Or he may obtain a sufficient volume of light for the purpose by reflecting light from above upon submerged reflectors. *Patent completed.*

2581. B. Hotchkiss. *Atmospheric trip hammers.* Dated September 20, 1862.

The object of this invention is chiefly to regulate the blow of the hammer and give elasticity to the parts, so as to give an elastic blow with the hammer, and at the same time prevent the breakage of the parts, which is one of the chief difficulties in the operation of trip and steam hammers. This hammer is provided with an air cylinder in which a piston is permitted to move and act upon air contained in the piston, in such a manner as to cushion the effect of the blow, and give it a portion of elasticity. The piston rod in this machine extends down from the piston in the air cylinder, and is connected below to the hammer. We cannot give space to the details of the invention. *Patent completed.*

2582. L. Dixey and G. Smith. *Tinting by lithographic printing photographic portraits and backgrounds, and embossing the same.* Dated September 20, 1862.

This invention is carried out as follows:—Having procured a good negative photograph in the usual manner, the patentees carefully block out the background with opaque colour or paper, in such manner that the background shall not print, but remain on the printed photograph white. After having procured a print off the negatives with a white background after the manner described, they fix, tone, and wash in the usual way with careful printing, and thus obtain a photograph ready for the following tinting, embossing, and colouring. They first lay the photograph upon a flat board, and upon that a piece af tracing paper large enough to cover the photograph; then with a lead pencil they trace carefully the outline of the photograph, which done, they remove the tracing paper, and cut out the line of the photograph which they wish to preserve from the tint about to be applied; they fix this upon the photograph by a little gum, carefully registering the outline of the photograph, for where this tracing paper does not cover there will be the tinting which was intended only for the background, and not for the portrait or landscape photograph. This being done, the tint of the desired colour is rolled on the lithographic stone and printed all over the photograph in the usual way of lithographic printing; the tracing paper which was fixed to the photograph, having prevented the ink from touching the print, may now be removed with a damp sponge. They then have a photograph with an evenly tinted back ground, and should they desire to give the print a tint all over of any lighter colour, they print again with the lithographic press all over the picture unprotected by the tracing paper, and which in some instances improves the general line of the photograph. 2, The photograph may now be embossed to give it the appearances and advantages of drawing paper. *Patent completed.*

2583. J. Wilson. *Composition for preventing and removing incrustation in boilers.* Dated September 20, 1862.

This invention consists in the employment of chemical precipitants for the lime and solvents for the silica, together with the materials which prevent the precipitate formed from caking and adhering to the bottom and sides of the boiler or tubes. The patentee employs a mixture of ground malt and woody fibres and other ligneous matters, also ground together with a caustic or a carbonated alkali and oxalate of ammonia. The latter two precipitate the lime and silica, while the malt and ligneous matters, aided by the constant ebullition in the boiler, prevent the precipitate from settling and incrusting. *Patent completed.*

2584. A. Prince. *Improvements in steam boiler and other furnaces, and in apparatus for feeding the same.* (A communication. Dated September 20, 1862.

This invention consists in certain improvements in the construction of furnaces, and in apparatus for supplying them with fuel, the object being that at every part of the surface of the grate the thickness of the layer of coal shall be regulated in an inverse ratio to the quantity of air required for its combustion, according to its condition of incandescence, and of its freshly-supplied coal or coke. The invention cannot be described without reference to the drawings. *Patent completed.*

2585. C. Mertens. *Improvements in machinery or apparatus for scutching and dressing flax, hemp, &c.* Dated September 22, 1862.

According to one part of this invention, the flax, hemp, or other fibrous materials to be scutched, cleaned, or dressed, are placed in hinged spring holders, which hold the fibrous materials firmly about midway of their length. These spring holders are placed on a table side by side, the ends of each holder being furnished with a sliding bolt and catch, and when the two parts of the holder are folded together with the fibrous material between them, the two ends of the holder are pressed together by a lever attached to the table, so as to allow the sliding bolt to be moved into a catch to connect the parts, and thus nip and hold the fibres firmly between them. Holders containing the fibrous materials may be passed by means of an endless chain or other mechanical means in continuous succession through the scutching machine, by being introduced between suitable guides at one end thereof, and as they pass out of the guides at the other end with part of the length of fibres scutched or cleaned, they are taken successively to the table before mentioned, and the cleaned ends of the fibres are laid over an open holder, which is then closed thereon, and secured as above described, the unclean ends being released from the first holder. The holder is then passed through the machine, as before described, so as to present the unclean ends to the action of the beaters, thus causing the fibres to be cleaned or scutched from end to end. *Patent completed.*

2586. J. Saunderson. *Improvements in writing desks and cases.* Dated September 22, 1862.

This invention relates to those desks known as "tourists," and "students'," and other like portable desks and cases, and consists in constructing such desks with two uprights to form the sides of the desk. The inventor places between these uprights compartments for holding paper, envelopes, and instruments, and he provides one or more drawers at the lower part or bottom of the compartments. He provides a pocket flap or not, as may be required, at the back of the case, and the folding flap - which is now formed of a single solid piece—he makes double and hollow to contain papers, letters, and the like. He also forms spaces in the back of the flap for containing ink and light holders. When closed the folding flap fits against the compartments and between the uprights, and a flap is brought over the top and secured in a lock or catch on the outside of the folding flap. *Patent abandoned.*

2587. H. Holdsworth. *Improvements in the manufacture of crinoline steel.* Dated September 22, 1862.

Provisional protection has not been granted for this invention.

2588. J. Long. *An improved machine for cleansing and scraping streets, roads, or ways.* Dated September 22, 1862.

This invention consists in adapting certain improved mechanical arrangements within a rectangular-shaped vessel, mounted on sliding wheels, so placed and adjusted as to allow one end to be near to the surface of the road, street, or way to be cleansed or scraped, and the other end to be connected temporarily to an ordinary cart to receive the dirt raised by the machinery, the said machinery being arranged and actuated as follows:—Within the aforesaid rectangular-shaped vessel, and crosswise thereof near its ends, two square shafts are mounted, so as to revolve. Over these shafts endless chains (formed of links each of the length of the side of the square shaft aforesaid) are passed, and have affixed thereto at certain distances from each other scoops of sheet metal. The hindermost of the aforesaid square shafts has a pair of running wheels fixed thereon, which, as they roll on the surface of the road, street, or way, impart rotary motion to the endless chains and scoops. The dirt is collected by spring scrapers mounted loosely side by side on a spindle fixed to the hindermost end of the rectangular receiving vessel aforesaid, the said end being made curved to allow the scoops aforesaid to remove therefrom the dirt which enters the same, and carry it forward and deposit the same in the cart before stated designed to receive the dirt. Beneath the bottom of the receiving vessel aforesaid, a false bottom is fitted and connected by levers at each side to the curved end of the said receiving vessel, the said curved end being moveable upon the axis of the running wheels aforesaid by means of curved toothed racks and sectors worked by the hand, for the purpose of keeping the scrapers aforesaid always in proper contact with the surface of the road, street, or way, as the sliding wheels of the receiving vessel are simultaneously moved either forward or backward, to alter the elevation of the front end of the receiving vessel aforesaid, either for connecting same to the receiving cart, or disconnecting same therefrom. *Patent completed.*

2589. W. McI. Cranston. *Improvements in machinery for reaping and mowing corn and other crops.* Dated September 22, 1832.

For these purposes, in order that a crop, as it is cut by a machine, may be raked back or off the table or platform of the machine, endless chains or bands are applied, to carry a rake or rakes. In carrying out the invention, it is preferred to use two endless chains or bands to a reaping or mowing machine, one on each side of the table or platform on to which the crop as it is cut is received. The ends of the rake or rakes are attached to the two endless bands or chains, to which continuous motion is given from the working parts of the machine. In order that the cutter bar of a reaping or mowing machine may be stopped and started under more favourable circumstances, the inventor applies a spring or springs, by preference of vulcanized india rubber, and stops in such manner that the cutter bar may be partially arrested by such stops and springs before it comes to the end of its stroke. *Patent abandoned.*

2590. M. Vogl. *Improvements in fastenings for leggings and other articles of wearing apparel.* Dated September 22, 1862.

According to the first arrangement, the patentee constructs a fastening, of which one portion or member is a pin, stud, or piece, having a head, outer end, limb, or part broader than, or projecting from its stem, shank, or body; this pin, stud, or piece is capable of turning wholly or partially round. The other member or portion of the fastening is a slot or opening, preferably edged or protected by a metal eyelet or rim. To effect the fastening, the pin or turning piece is introduced into the slot or opening, and turned sufficiently to bring its head, outer end, or projecting limb at an angle to the length of the opening or over its edge or side, in which position the members of the fastening are engaged. To disengage them, the pin or turning piece is turned so as to bring its end, head, or limb in such position with regard to the slot or opening that it can be slipped through the same. Or, in a second arrangement, he uses, instead of the pin, stud, or turning piece, a spring or springs of such shape and arrangement that, when compressed, it or they may be passed through the slot or opening; but when released or allowed to extend or return to its or their previous form, the arms or sides of the spring will project or extend over the sides or edges of the slot or opening, and effect the fastening. The spring may, if desired, be capable of turning wholly or partially round. *Patent completed.*

2591. J. and D. Mapple. *Improvements in telegraphic apparatus.* Dated September 23, 1862.

This invention consists of a flat endless chain rotated by a train of clockwork, and in its rotation it is made to rub against an inking roller supplied with printing ink, and so forming a tracer. A strip of paper is likewise carried forward by the said clockwork, and the strip of paper is made to rub continuously against the tracer, and the contact of the tracer with the paper is broken; or the paper is pushed away from the tracer as may be desired to give the signals by the attractive force of an electro-magnet, which magnet pulls an arm down and presses the paper away from the tracer, in contradistinction to W. Spence's patent communicated to him by Digney Frères (No. 279) of 1858, in which the arm moved by the electro-magnet presses the strip of paper against the tracer. The inventors purpose reading the telegrams by the white spaces instead of the inked lines of other tracing instruments, as by this arrangement the instrument is capable of being worked with a smaller amount of power than any other tracing instrument. *Patent abandoned.*

2592. R. Fairbairn. *Improvements in machines for combing wool or other fibrous substances.* Dated September 23, 1862.

This invention relates—1, to the transfer comb, carrying comb, or porter comb motion; and the improvements consist in the application thereto of a friction box or pair of flanges or collars with a washer of leather, india rubber, cloth, or other flexible material, placed betwixt to produce friction, the amount or degree of which is adjusted or regulated by a spring. By this means the inventor prevents that trembling of the comb which is now experienced when it is brought up to the "nip," or into contact with the nipping apparatus. 2, This invention relates to the nipping motion, and consists in the application of slide bosses and adjusting screws for attaching the cross bar on which the upper or top jaw moves, by which means the said top jaw can readily be set, adjusted, or regulated to the groove of the lower jaw, so as to obtain perfect parallelism thereof. *Patent abandoned.*

2593. T. and W. Knowles, and J. and W. Houghton. *Improvements in looms for weaving.* Dated September 23, 1862.

This invention relates,—1, to the box motion or to a means or method of working the rising boxes in looms for weaving, and consists in combining and arranging mechanism or apparatus for that purpose as follows:—At each end of the loom a tappet is fixed on the low shaft which operates upon the side-plates or brackets, capable of sliding in fixings attached to the loom framing. These slide plates support lifting horns or arms, which are capable of being operated by rods and levers from peg-lays or jacquard apparatus, and caused to take into one or other of a series of notches attached to or formed on levers which are hinged to the framing, and connected by rods to the rising boxes, which are thereby operated and brought into position, according as they are indicated and actuated by the peg-lays or jacquard apparatus. 2, This invention relates to the picking motion, and consists in combining and arranging apparatus for that purpose as follows:—An eccentric is fixed on the crank shaft (at each end of the loom) operating a slide bar or rod, on which is hinged a pair of horns or arms, capable of being operated by peg-lays or jacquard apparatus, and thereby brought into contact with one or other of two nibs or projections formed on a lever plate hinged to the framing, and according to the action upon which the picking lever is moved into or out of contact with the picking noses or picking tappets. 3, This invention relates to a lagging-back motion or means of turning back when the weft breaks or becomes used up. *Patent completed.*

2594. C. Pontifex. *Improvements in means or apparatus for removing or expressing beer from yeast or from hops.* Dated September 23, 1862.

For the purpose of carrying out these improvements the inventor takes a box, back, or other receptacle of suitable shape, which he mounts by preference upon four wheels; these wheels are made with the outer circumference hollow, which hollow is used as hereafter described. At a proper distance from the bottom of the box or back he places a shelf of wood of sufficient strength, which shelf is constructed with ribs on its surface to allow the escape of liquids when in use. A second shelf (or any other number of shelves may be used) is arranged to fit inside this box or back, and is provided likewise with grooves or ribs on its upper and under surface, and it is arranged to slide freely through the box. An upper or top shelf also is made, but arranged to pass to a certain distance down into the box or back, and then rest on the side of the box. To extract the beer from yeast or hops he takes a bag or bags made of canvas of the description ordinarily used for fining wine or beer, and of a length sufficient to fill up the length of the box or back before alluded to. He fills this bag with the yeast taken from "stillions," or from the "working tuns," and fastens the neck thereof when sufficiently full in any convenient manner. This bag is laid horizontally on the bottom shelf of the box or back, the middle shelf is then put in its place, a second bag similarly filled is then placed on the middle shelf, and the top shelf is then placed in position, and the beer is pressed out by weight or pressure applied to the top shelf. *Patent abandoned.*

2595. W. Dobson. *A new method of producing various colours on lace or other fabrics.* Dated September 23, 1862.

This invention has for its object the production of various colours on lace or other fabrics, whether made of silk, cotton, or other material. Hitherto it has been usual, when dressing lace fabrics (or other fabric), to dress each of them of one colour only, whereas this invention consists in the employment of various coloured dyes for one and the same piece of lace or other fabric, by which means the lace or other fabric acquires any required colours. *Patent completed.*

2596. J. J. N. Micas. *An improved railway break.* Dated September 23, 1862.

This invention consists in certain new and improved mechanical arrangements and combinations of parts so disposed and arranged as to be self-acting, and to operate in the running wheels of a railway train in such a manner as to interpose wedge-shape pieces of metal between the peripheries of the wheels and the surface of the rails on which the said wheels run, thus locking the wheels, and causing friction on the rails, so that the train slides or skids thereon. *Patent completed.*

2597. R. A. Brooman. *Improvements in lighting apparatus.* (A communication.) Dated September 23, 1862.

This invention consists of apparatus for reflecting, refracting, or amplifying light, composed of several prismatic curved or lenticular faces or mirrors, made to rotate round a fixed body of light sufficiently rapidly to cause the flashes of light to make a continuous impression upon the retina of the observer by sufficiently frequent periodical shocks, while the eclipses become unperceived by the observer. The rotary motion of this condenser of light may be continuous or intermittent, and may be produced by any mechanical force, such as clockwork. The light is stationary, and the luminous rays are, in whole or in part, condensed in a narrow zone; the lenses are prismatic or cylindrical to produce vertical bands of light. The light may be from oil or gas burners, or the electric or other artificial light may be used. There should be at least three faces or mirrors in the apparatus, but there should not be too many, about six is the most suitable number. Each of the faces receives a vertical luminous angle, which it transforms into a luminous band, also vertical. The apparatus does not increase the intensity of the light, but it amplifies the lighting through a lenticular refraction with entire destruction of dead angles—it projects the light to a distance. *Patent completed.*

2598. R. A. Brooman. *Improvements in photographic apparatus.* (A communication.) Dated September 23, 1862.

This apparatus enables the manipulator to operate in full light upon damp collodion, to sensitize the glass, and to finish the proof in the light. The apparatus does not alter the negative now used, but it serves as an auxiliary to it. In the apparatus the following characteristic elements are combined:—The employment of two vertical and independent bath vessels, arranged to allow of the glasses being easily plunged therein—one vessel containing the bath of silver for sensitizng the damp collodion, may be of gutta percha, hardened rubber, or other material having no action on the bath; the other, containing the iron bath for developing the picture, should be of yellow or orange-coloured glass; if made of any other material, it should be lined with yellow-coloured glass. There is a frame for holding the glasses to be exposed capable of being opened and closed at bottom by withdrawing or inserting a sliding bar. There is a second frame for holding the colodionized glass in the former frame, which second frame is styled the plunging frame, because it is used for introducing the glass into the bath vessels, entering also with it; it is insulated from the first frame and may be passed through it; a piece of catgut is attached to the plunging frame to raise and lower it into and out of the baths. *Patent completed.*

2599. S. H. Laurent. *An improved railway break.* Dated September 23, 1863.

This invention consists in the use of clamps which embrace and slide on the rails, power being exerted at a given moment to force them on the rails, and thus to oppose such resistance, almost in an instant, that the speed of a train is reduced to zero. *Patent abandoned.*

2600. W. Wilkinson. *Improvements in the manufacture of knitted elastic fabrics, and in the machinery employed therein.* Dated September 23, 1862.

Provisional protection has not been allowed for this invention.

2601. J. Farran. *Certain improvements in looms for weaving.* Dated September 24, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2602. W. Clark. *Improvements in signalling.* (A communication.) Dated September 24, 1862.

This invention relates to a universal system of signalling. The alphabetical transcription of words is replaced by the adoption of suitable signals, whereby the patentee effects the complete separation of words from their grammatical elements, such as prepositions, adverbs, or other parts of speech; the sign or signal for every word, such as a verb or substantive, and so on, is always the same, whatever may be the character of the word in the sentence, this character being indicated by a separate sign or signal, which points out the case, gender, number, tense, or the mood, and forms the verbs, adjectives, and adverbs, by being added to a substantive. The use of such grammatical signs or signals is reduced to a minimum. One single expression is substituted for several synonymous words, the simplest ideas alone being classed under signals; as for the complex ones, they are figured or represented by means of two or more signals themselves representing simple ideas. *Patent completed.*

2603. W. Taylor. *Improvements in blacking or polish.* Dated September 24, 1862.

In preparing this blacking or polish, the inventor takes slack coal (or its equivalent) reduced to fine powder (though he could, if desired, substitute or add ivory black, made by burning the bones contained in the pieces of flesh used by him), to which he adds indigo, and forms the same into a paste by mixing the following ingredients therewith, namely:—Fruits, such, for instance, as foreign fruits termed currants, raisins, dates, and the like, or any one of these reduced to a jelly; also animal jelly, such, for instance, as calves', cows', sheep or horses' feet, or any part of the flesh of animals that will reduce to a jelly; tallow, suet, or other fatty matter, and also acetic acid and lemon, the same being formed into a syrup by putting the lemons into the acid. *Patent abandoned.*

2604. R. A. Brooman. *An improved composition for painting.* (A communication). Dated September 24, 1862.

This composition, called "Neoline," is made by mixing two compounds, specially prepared and incorporated at the time of using. The first or liquid compound is composed of 750 parts of distilled water; 65 parts of oxalic acid; 60 parts of sugar, syrup, or other saccharine matter; 100 parts of alkali in salts or liquid (say, salts of tartar, soda, potash, ammonia, or other alkali, modifying the proportion according to the strength of the material used); and 25 parts of soft soap. The second or siccative compound is composed of 125 parts of white lead or zinc white, with barytes for its base or chalk; 125 parts of boiled drying oil; 250 parts of liquid siccative of any kind; 250 parts of zumatic (zumatique) white siccative in powder; 200 parts of soft soap (by preference mixed with silicate of potass or soda); and 50 parts of litharge. *Patent completed.*

2605. W. Maddick, jun. *An improved process or method of treating and preparing madder for dyeing purposes.* Dated September 24, 1862.

The patentee claims—1, treating madder for dyeing purposes after being ground by first saturating, damping, or wetting with water, and then allowing it to stand for anytime within 24 hours previous to or before it is placed in the dyeing bath or beck. 2, preparing madder for dyeing purposes by dyeing without pressure, or with limited pressure, after being treated as mentioned and claimed under the first head of the invention. *Patent completed.*

2606. D. and A. Posener. *Imporements in the manufacture of india-rubber and other tobacco pouches or purses.* Dated September 24, 1862.

In carrying out this invention the inventors propose to form the pocket of the pouch of the ordinary shape; but to ensure the safety of the contents, they add a flap to the mouth thereof, and instead of its being necessary for the cover of the pouch to be turned inside out, as is now the case, in order to enclose the pocket, they form the outer covering by cutting out a crescent-shaped or curved piece therefrom, in order that the pocket may be turned over, and its bottom part inserted or pushed under the curved opening, whereby it is easily retained. Thus, it is never necessary to turn the protecting cover inside out, the pocket of the pouch being merely folded over and inserted as just described. For tobacco pouches they propose to form a division in the centre of the pocket for the purpose of holding two different kinds of tobacco, the flap before mentioned covering both; or, to prevent the partial admixture of the tobaccos, the division may be continued into the form of a flap, or the flap or upper part of the division may be made in duplicate for the purpose of covering the mouths of both pockets. *Patent abandoned.*

2607. R. R. and A. I. Jackson. *Improvements in the preparation and treatment of flax and other fibrous materials to be subsequently operated upon by machinery employed for preparing and spinning cotton.* Dated September 24, 1862.

This invention has for its object the preparation and treatment of such fibrous material as is generally of longer staple than cotton fibre, so that such prepared fibrous material may be subsequently operated upon either alone or in combination with cotton or other fibrous material by such machinery as that commonly used for preparing, spinning, and weaving cotton alone; and the invention consists—1, in preparing flax, tow, or other fibrous material so as to be submitted to a carding process by any ordinary means, sometimes only to the extent necessary to put it to the tow card, and then carding the material, then operating upon the carded material by gill drawing combs to still further straighten the fibres if required; next, forming the material into a lap or sheet by means of a Derby doubler, or other suitable machine, and then cutting the laps or sheets into short lengths, by a machine similar to that described in the specification of a patent granted to the present patentees on the 24th day of September, 1862 (No. 2608), or any other suitable machine. When the fibrous material has undergone these processes, it is ready to be operated upon alone, or in combination with cotton, in ordinary preparing and spinning machinery for operating upon cotton fibre. *Patent completed.*

2608. R. R. and A. I. Jackson. *Improvements in machinery for cutting fibrous and other materials.* Dated Sept. 24, 1862.

This invention consists in certain modifications of machines which have been mostly used heretofore for cutting paper, such machine consisting of a knife which has either a vertical or a compound vertical and lateral movement, but the patentees prefer such as make a diagonal cut; the knives in these machines cut against or into lead or other soft metal or material. These improvements consist, namely, in combining a lattice or endless feeder with machines of the class above described to feed forward the material to be cut, which is made to pass between a pair of weighted rollers having intermittent motion imparted to them. *Patent completed.*

2609. W. Upfill and W. Asbury. *Improvements in the manufactnre of metallic bedsteads, part of which improvements are also applicable for ornamenting tubes and curtain and cornice poles.* Dated September 24, 1862.

This invention relates, in the first place, to that description of metallic bedstead in which the side and bars and rails are connected to the corner pieces by means of dovetailed joints, which have heretofore been made of cast-iron, and, consequently, have been exceedingly liable to breakage at at these parts, and when thus damaged the broken parts are useless. The first improvement consists in forming the dovetailed ends of the side and top and bottom angle iron rails or bars of wrought iron, instead of casting the dovetails on the ends of the angle iron rails as heretofore. The second part of the invention relates to a novel mode of ornamenting these tubes, posts, or pillars, and consists in covering them externally with perforated metal cut or punched out with any device. *Patent completed.*

2610. T. Edwards. *An improved mode of preparing fibrous materials for spinning.* Dated September 24, 1862.

In carrying out this invention, the inventor takes linen and cotton rags, and having carefully sorted them, he submits them to a series of operations, whereby they will be reduced to a state of separate filaments. The first operation to which he proposes to submit the rags after sorting them is, to a beating or tearing action in a machine constructed after the principle of the machine well-known in the cotton and woollen trade as the "devil." In this machine the woven threads will be torn asunder and brought to a state of loose filaments. These filaments he conducts to a carding engine for the purpose of carding out the same and reducing them to a state of fine fibres. The carding operation may be repeated until fibres of the requisite fineness are obtained, and he then converts the product into rovings, which will admit of being spun in the usual way of spinning cotton. *Patent abandoned.*

PROVISIONAL PROTECTIONS.

Dated Nov. 28, 1862.

3194. W. Buller and J. H. Mugford, Bovey Tracy, Devon. Improvements in spur supporting rings for fixing plates, dishes, and other like articles in glost ovens.

Dated Dec. 16, 1862.

3364. H. Jörns, Tessin, Grand Duchy of Mecklenburgh Schwerin, watchmaker. Improvements in clocks or timepieces.

Dated Feb. 4, 1863.

318. W. T. Weston, 4, Trafalgar-square, Charing-cross. An improved spring catch or fastening applicable to windows and other useful purposes.

Dated March 5, 1863.

628. W. Clark, 53, Chancery-lane, engineer. Improvements in firearms. (A communication).

Dated March 6, 1863.

641. H. R. Spicer, 3, Clement's-lane, Lombard-street. Improvements in protecting and preserving the bottoms and sides of ships and other submerged surfaces from oxidation or fouling by incrustation, the attachment of barnacles, the action of animalculæ, or from any other like causes of injury.

Dated March 17, 1863.

716. W. E. Newton, 66, Chancery-lane, civil engineer. An improved preparation for the cure of scab, foot-rot, and other diseases of sheep and cattle. (A communication.)

Dated March 21, 1863.

757. E. Hartley, mechanical engineer, J. Clegg, machinist, and T. and J. Mellodew, manufacturers, Oldham. Improvements in looms for weaving.

759. F. Applegate, Bradford-on-Avon, Wilts, woollen manufacturer. Apparatus for making certain indications in railway carriages.

Dated March 23, 1863.

762. H. Hancock, 208, High-street, Southwark. A new combined range for making gas, cooking by gas, and lighting, especially applicable for ships.

763. J. W. H. and E. J. Rothwell, Ramsbottom, Lancaster, cotton spinners. Improvements in heating the feed water of steam boilers.

765. T. G. Grant, Royal Clarence-yard, Gosport, Hants. Improvements in ovens, and apparatus for heating the same.

767. W. Clark, 53, Chancery-lane, engineer. Improvements in agricultural apparatus. (A communication).

Dated March 24, 1863.

769. J. Reilly, New Globe Chair and Cabinet Works, Barrack-street, Hulme, Manchester, and W. Martin, Manchester. Improvements in lubricating horizontal shafting and bearings of all descriptions.

771. S. Healey, Elizabeth-street, Hackney-road, engineer. Improvements in the manufacture of zinc, and in the apparatus employed therein.

773. A., J., and J. Topham, St. Pierre les Calais, France, lace manufacturers. Improvements in the manufacture of ornamental twist lace, and in machinery used therein.

775. A. J. Cooke, Crown-court, Bow-street. Improvements in portable "Hooka" pipes.

Dated March 25, 1863.

777. M. Phillipps, Dewsall, near Hereford, engineer. Improvements in the manufacture of iron or other metallic rod and wire, and in the machinery or apparatus employed in such manufacture.

779. J. H. Worrall, Bacup, Lancaster, surgeon. Certain improvements in the method of producing surfaces in imitation of woods, and in printing therefrom.

781. C. Monson, New Haven, Connecticut, U.S. An improved gravitation engine.

783. J. H. Johnson, 47, Lincoln's-inn-fields, gentleman. Improvements in the manufacture of zinc, and in the apparatus employed therein. (A communication.)

785. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in the manufacture of cords, ropes, and cables, and in machinery employed therein; applicable also to spinning, winding, and twisting fibrous and filamentous substances. (A communication.)

Dated March 26, 1863.

790. M. L. Parnell, 283, Strand. Improvements in the construction of locks, and in the method of adjusting their spindles.

Dated March 27, 1863.

802. W. M. Morgan, Kidderminster, Worcester, manufacturer. Improvements in coating metals, and in machinery and apparatus employed in coating metals.

804. J. Taylor, jun., Parliament-street, Westminster. Improvements in the construction and arrangement of the rain water pipes of buildings.

Dated March 28, 1863.

808. B. W. Goode, St. Paul's-square, Birmingham, manufacturer. A new journal, axle, or bearing, particularly applicable to rolls.

810. R. Sims, Bedford Foundry, Leigh, Lancaster, agricultural implement maker and iron founder. Improvements in reaping and mowing machines, part of which improvements are applicable to horse works.

814. G. Thomas, 50, Chichester-villas, Kilburn-park, Middlesex, builder. Improvements in window shutters and window blinds.

Dated March 30, 1863.

816. J. Musgrave, Globe Works, Bolton, Lancaster, engineer. Improvements in the construction of steam boilers.

818. R. Mushet, Coleford, Gloucester, metallurgist. An improvement or improvements in moulds to be used for casting steel or homogeneous iron.

820. J. Carver, The Butcher-street Works, Nottingham, bobbin and carriage manufacturer. Improvements in the manufacture of carriages employed in machines for the making of lace or other fabrics.

Dated March 31, 1863.

824. E. T. Hughes, patent agent, 123, Chancery-lane. An improved composition for rendering cloth, paper, and similar articles transparent and waterproof. (A communication.)

826. A. B. D. Maurand, No. 15, Passage des Petites Ecuries, Paris, gentleman. A translucid cylindric apparatus for bringing the former weights and measures into those of the present decimal system most easily and precisely, and *vice versa*.

828. W. Forrest, cotton spinner, and H. Duckworth, machinist, Blackburn, Lancaster. Improvements in looms for weaving.

832. H. Hamer, Kender-street, Old Kent-road. Improvements in tanning, and in apparatus employed therein.

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

From the *London Gazette*, April 14, 1863.

3194. W. Buller and J. H. Mugford. Spur supporting rings for fixing plates, dishes, and other like articles in glost ovens.

3212. H. L. Emery. Thrashing machines.

3219. J. Romer. Manufacture of bullion wire and metallic fine drawn wire.

3229. J. and J. Craven and J. Robinson. Looms for weaving.

3232. T. Cook. Envelope-folding machinery.

3239. B. Browne. Construction of knobs or handles of door locks, and in the mode of connecting same with the sliding bolts thereof for advancing and drawing back said bolts. (A communication.)

3243. C. F. Claus. Carboy hampers, and in the machinery or other means for manufacturing the same.

3256. J. Robinson. Construction of ships and vessels.

3260. T. G. Webb. Manufacture of articles of pressed glass.

3267. W. J. Smith. Manufacture of collars, cuffs, and wristbands.

3270. H. A. Bonneville. Manufacture of stockings and socks. (A communication.)

3271. R. Thorp. Coating or covering for steam boilers and other surfaces to prevent the radiation of heat.

3272. J. C. and M. Craig. Apparatus for the manufacture of clay.

3274. W. McNaught. Machinery for washing and drying textile fabrics and materials.

3281. W. Palliser. Screw bolts.

3287. G. A. Huddart. Buttons.

3293. J. A. and C. L. Kiesling. Means of renewing worn-out and partially work-out files and rasps.

3295. T. Wingate, jun. Dredging machinery.

3299. R. A. Brooman. Treating liquorice root. (A communication.)

3300. G. Jeffries. Breech-loading firearms.

3306. J. Lamb. Tissue paper.

3307. W. Inglis. Steam boilers.

3310. S. B. Whitfield. Dovetail joints.

3312. A. P. Price. Blue colours. (A communication.)

3322. R. Clark. Apparatus for boring, winding, and lifting for mining purposes.

3324. J. Imray. Apparatus for mixing and kneading.

3326. T. E. Vickers. Construction of ordnance.

3329. J. E. Roussel. Looms for weaving. (A communication.)

3339. C. Corbet. Rails for railways, and in the mode of forming the joints of the same.

3348. G. Buchanan. Crushing sugar canes.

3374. T. C. Barraclough. Spinning, twisting, and rolling tobacco. (A communication.)

3383. E. Lepainteur. Fabrication of a salt for dyeing textile materials.

3392. S. C. Lister. Preparing, combing, and spinning flax, silk, and other fibrous materials.

3393. A. V. Newton. Transmitting power. (A communication.)

3415. G. E. M. Gerard. Fabrication of threads from vulcanized india rubber.

3438. W. Henderson. Obtaining iron and steel from certain ores and residual products.

3473. H. A. Bonneville. Manufacture of saddles. (A communication.)

79. E. T. Hughes. Apparatus for printing or staining woven fabrics, warps, paper, and other articles. (A communication.)

118. J. S. Butler. Manufacture of bobbin net made on bobbin net or twist lace machines.

262. H. A. Bonneville. Construction of granaries. (A communication.)

306. T. L. Jacobs. Apparatus for cleaning casks.

716. W. E. Newton. Preparation for the cure of scab, foot-rot, and other diseases of sheep and cattle. (A communication.)

770. G. Davies. Wrappers or papers for needles, and in machinery or apparatus for sticking needles therein. (A communication.)

779. J. H. Worrall. Producing surfaces in imitation of woods, and in printing therefrom.

798. W. Blake. Labels for luggage and other articles.

The full titles of the patents in the above list can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners' office particulars in writing of the objection to the application.

LIST OF SEALED PATENTS.

Sealed April 13, 1863.

2570. S. Chatwood.
2751. G. Harvey and A. Harvey, jun.
2752. A. F. Gallis.
2755. W. Loeder.
2766. J. Snider.
2769. M. Cartwright.
2770. R. A. Brooman.
2772. E. H. C. Monckton.
2773. O. J. and J. Showell.
2777. W. Wilson.
2779. J. Taylor.
2782. W. Pope.
2788. R. A. Brooman.
2797. E. Humphreys.
2798. H. Ransford.
2800. J. Robinson.
2802. E. Nelson.
2803. J. Summerton.
2804. H. Wickens.
2813. B. Lauth.
2815. J. Fuller.
2846. H. H. and J. F. Kromschroeder.
2863. A. J. F. Vigneulle-Brepson.
2885. J. H. Johnson.
2921. J. Unsworth.
2930. G. Piggott.
2937. W. R. Bowditch.
2959. W. E. Newton.
3111. J. B. Edmondson, J. Carson, and J. Blaylock.
3282. G. Lowry.
3443. E. Stevens.
8. J. Jones.
121. B. Burrows.
199. R. Penney.
301. T. Raworth.

PATENTS ON WHICH THE STAMP DUTY OF £50 HAS BEEN PAID.

898. W. E. Newton.
887. H. Bridle.
923. J. Hill.
895. L. J. Repelin.
899. J. Rigby and W. N. Norman.
924. A. Bamlett.
1064. J. Bullough.
935. M. A. F. Mennons.
991. T. G. Dawes.
905. T. H. P. Dennis.
960. C. Vaughan, W. J. Vaughan, and R. Vaughan.
1107. M. Bonnor.

PATENTS ON WHICH THE STAMP DUTY OF £100 HAS BEEN PAID.

846. W. H. Gauntlett.
902. W. Fuller.
915. H. Y. D. Scott.
895. H. F. Forbes.
1124. H. Tucker.

The *Illustrated London News* of November 8th, when describing Benson's Great Clock says: "The movement of this clock, next to that of Westminster, is the largest in the world, and in point of quality of material, and finish of workmanship, it is unequalled by any known." Benson's new show rooms contain clocks designed by the first artists of the day, and include clocks for the drawing-room, dining-room, bed-room, library, hall, staircase, bracket, carriage, church, turret, railways, warehouse, counting house, with musical, astronomical, and every description of clock from the plainest to the highest quality of which the art is at present capable. Church and turret clocks specially estimated for. Benson's Illustrated Pamphlet on Clocks and Watches (free by post for two stamps) contains a short history of clock and watch making, with descriptions and prices. It acts as a guide in the purchase of a clock or watch, and enables those who live in Scotland, Ireland, Wales, the Colonies, India, or any part of the world to select a clock.—J. W. BENSON, received a Prize Medal and honourable mention.—33 and 34, Ludgate-hill, London. Established 1749.—[Advertisement.]

THE

MECHANICS' MAGAZINE.

LONDON, FRIDAY, APRIL 24, 1863.

DISTORTED INDICATOR DIAGRAMS.

In most scientific and practical arts there are certain instruments that indicate the right course to be pursued in overcoming any given obstacle, and upon the right usage of which more or less depends the success or the failure of the special practitioner. We run little risk of contradiction in asserting that what the stethoscope is to the physician, the boring-rod to the miner, the hydrometer to the distiller, the blowpipe to the chemist, the indicator is to the steam engineer. It is only by a proper employment of this inestimable instrument, that tolerably true deductions, as to the internal working of an engine, can be arrived at with any degree of certainty—that a correct diagnosis can be formed as to the real state of the iron patient. Such being the case, it is perhaps surprising that more attention has not been directed to certain influences that in some cases undoubtedly distort an indicator diagram. These disturbing actions may be greatly modified by the construction of the indicator itself; they may be decreased or diminished by a proper or improper construction of the instrument; but these influences will always exist to a greater or less extent, and some allowance should be made on their account, before the diagram be accepted as a perfectly true picture of the performance of the steam in the cylinder.

The steam-engine indicator is especially liable to several objections when used for determining forces acting with great velocity and suddenness. The inlet of the steam is generally throttled by the narrowed apperture of the cock, and the indicator piston in its sudden ascent has to meet the column of air above. In the ordinary instrument there is a long and tremulous spring, which, from its length and weakness, is somewhat liable to rub on one side in the casing. The working parts are also often made unnecessarily heavy. When steam of a high pressure is let on to the indicator piston, the spring gives way and is suddenly thrown up; this action is aided by the momentum of the other moving parts; the pencil continues to oscillate during the remainder of the stroke; and the natural result is a jumping, serrated, zig-zag diagram. The total power indicated by the diagram is, perhaps, not very far from exactitude, as the action and reaction are probably about equal; but the most important function of the indicator consists in its giving the true performance and progressive course of the steam in the cylinder, and it is evident that, under such circumstances, the lines of the diagram have not that accuracy that is demanded by the importance of the deductions the experimenter wishes to obtain.

There is no doubt that the larger the indicator the better, other things being equal. The friction of the piston and of the moving parts is less in proportion; the cock and pipe are larger, the steam is thus less liable to be throttled in its passage to the piston, &c., and the divisions on the scale and the diagram itself being of a larger size, there is less chance of error. Watt used very large indicators, with powerful springs and a short throw of piston. It is stated that Watt obtained the scale of pounds by actual trial of weights pressing down the spring; but these results were taken while the indicator was cold, and, therefore, in a very different state, and in a different relation of the parts by measure than when the instrument is doing its work. It is evident that a more correct way would be to apply the weights on the top side of the piston while the indicator is fixed on the cylinder of an engine; the instrument being then in the same state as when performing its proper functions, the spring is of the same size and of the same elasticity as when in use, the whole apparatus on at a similar temperature, and the piston is lubricated with the same quantity of oil.

The weights being, one after the other, applied to the top of the piston, the atmospheric line and the gradual descent of the piston are then recorded by the pencil of the instrument and the principal divisions are thus obtained for a complete subdivision, and a true scale is the result. We should be glad to know how the principal manufacturers of indicators graduate the instruments, upon the exact performance of which so much depends. Perhaps the most exact way would be to use a properly-graduated mercurial column. There would certainly be some difficulty with this plan with an indicator for very high pressure. Mr. Parkes, the civil engineer, found that the pressures for the scale of the indicator were more correctly obtained by comparing them with a mercurial column than by ascertaining them by means of weights—"The instrument being then heated, was then in precisely the same state as when it was in use." He also found that a certain amount of correction was frequently necessary, as both the spring and the amount of piston friction were affected by heat.

According to Professor Moseley, the scale of ordinary indicators should not always be in equal divisions, because the wire of the spring being wound spirally into a screw of small diameter, the spiral obliquity of the thread of such a screw becomes "more oblique to the direction of the bending force as the spring is stretched, and less oblique as the spring is compressed, and hence the scale of pounds per square inch, by which the curve should be measured for summing up the results, ought to be a scale of unequal divisions."

Having thus alluded to a few points in the construction of this important instrument, that appear to us as being sometimes neglected by the makers, we will mention one probable source of wrong results more under the control of the experimenter. As is well known, the part of the engine giving motion to the string of the indicator ought always to be as near the instrument as possible, as otherwise the string will slacken, and the barrel will thus be stationary for an interval, of course the result being a wrong diagram. As it is of such great importance that the string attached to the indicator barrel should neither be too slack nor be too tight and liable to stretch, it has sometimes occurred to us that it might be advisable to use a kind of string worked up with fine wire, similar to the tape measures that are sold for measuring lengths of 30 or 40 ft.

There is also sometimes a danger to the exactitude of the diagram from the steam getting condensed. The most convenient way of taking a double diagram is by fixing the indicator to a pipe leading from the top to the bottom of the cylinder. This pipe being fitted with stop cocks, the two diagrams can be taken almost simultaneously. The great objection, however, to this plan consists in the natural tendency of the steam to get condensed in this small pipe.

There are, however, disturbing influences in the diagram of an indicator that are more beyond the control of maker and user of this useful instrument, and which do not seem to have been, as yet, thoroughly investigated by the writers on, and experimenters with, the steam-engine indicator. We allude to the partial vacuum created by the motion of a fluid, and at right angles to its course. We believe that this phenomenon was first noticed by Mr. Richard Roberts, the well known engineer, while making some experiments with a blowing engine in Manchester, in the course of the year 1826. This action may be easily and familiarly illustrated by placing a sheet of paper on the inside of the hand, and blowing from the back of the hand through the spaces between the fingers. The paper, instead of being blown away, as might be expected, is kept up against the palm of the hand by the partial vacuum between the palm and the paper, caused by the rapid and diverging current of air. This would seem to point to the necessity of placing the indicator on the cylinder at such a place, that it may be as little as possible influenced by the motion of the steam out of the ports into the steam pipes. This deteriorating influence on an indicator diagram would be more likely to occur on the vacuum side of a condensing engine, from the great speed of the steam rushing into a vacuum, than on the steam side. It would not improbably affect to some extent the diagram of a high pressure engine working at a high speed. There is another inquiry, no less interesting, as to the exact effect on a diagram of the speed of the piston. There is, of course, always sufficient time for the steam to follow the piston at full pressure if the piston moves slow enough; but at a higher speed, there is an undoubted reduction in pressure of the steam as it expands behind the piston.

Again, when a pair of coupled engines exhaust into one blast pipe, there is probably a reciprocative intermittent action of the back pressure of the two exhausts on the exhausting sides of the pistons.

The exact value of the objections we have raised against the accuracy of this important instrument could only be ascertained by means of a series of carefully conducted experiments; that these objections are more or less tenable, will be evident on reflection.

H.

CAST STEEL STEAM BOILERS IN PRUSSIA.

"We may be assured that, so certain as the age of iron superseded that of bronze, will the age of steel reign triumphant over iron." Such were the closing and doubtlessly prophetic words of the remarkable lecture on steel, delivered by Mr. Bessemer, July 31st, 1861, to a meeting in Sheffield of the Institution of Mechanical Engineers. In that instructive paper Mr. Bessemer described, in terms worthy of the subject, his extraordinary discovery—a discovery, according to Mons. Michel Chevalier, of more value to the world than all the gold mines of California. Great discoveries and inventions generally run in parallel lines, and help each other in their onward march. Thus, the inventions and discoveries of John Wilkinson and Henry Cort in the manufacture of iron; the spinning machinery of Hargreaves, Arkwright, and Crompton; the steam engine of Watt—all took their rise at about the same time. Each of there inventions was more or less dependent on the others, and they all in concert furthered each other's progress. Now the main direction towards which steam engineering practice has been tending ever since the time of Watt, has been the employment of high pressures of steam. The great resulting economy of fuel, and the reduction of first cost of the whole apparatus, are not the only advantages to be obtained by the use of high pressures.

The weak side of the steam apparatus, considered as a whole, has undoubtedly been the boiler. Wrought iron, the material generally employed in these structures, is always, from the peculiar manufacturing processes employed in its production, of a more or less treacherous character. This is more especially the case when wrought iron in the form of rolled plates is used in boiler-making. When the "puddled ball" has been reduced under the blows of the hammer and the pressure of the rolls into its ultimate shape, its congeries of welds or joinings will be drawn out by the above processes in the direction of the length. The strength of the plate, therefore, will be little affected as regards longitudinal strains in the direction of the fibre. Not so, however, if the plate be subjected to an explosive or rending force from the interior, as in a boiler. To use the graphic words of Mr. Bessemer himself:—"The extremely high temperature requisite to maintain malleable iron in a state of fusion, has, from the earliest period of the history of iron up to almost the present day, rendered its purification in a fluid state practically and commercially impossible; hence arise all those imperfections to which bar iron is subject—every small piece of this material consisting of numerous granules partially separated from each other by scoria, and every large mass of it resulting only from the piling together of small bars, with the inevitable result of increasing the former imperfections; for no two pieces of iron can be brought to a welding heat without becoming perfectly coated with oxide, and when this coating is rendered fluid by welding sand, a fluid silicate of the oxide of iron is formed, covering the entire surface to be united. The heavy blows of the hammer, or the pressure of the rolls, may and does extrude the greater portion of this fluid extraneous matter, but it is never wholly removed from between the welded surfaces, and hence a portion of the cohesive force of the metal is lost at every such junction." Nothing of this takes place with cast steel manufactured by the modern process. Its almost perfect continuity, and the absence of all welds, evidently point it out as the true material for steam boilers. Any flawed wrought-iron plate built up in a boiler will very soon bend and buckle under the action of the fire. The temperature of the surface of a boiler plate in contact with the fire diminishes with the thickness; and the thinner steel plate is thereby enabled to better stand the fire, for the very reason that it is thin. Thus far, regarding only the strength of a steel boiler, there could be little doubt, that, tried merely by the hydraulic test, a boiler of steel would stand a much higher pressure than one of wrought iron. Natural fears, however, were at first entertained that steel plate might change its character under the influence of fire on one side and of water on the other. Only careful observations and experiments, extending over some years, could raise the not unnatural doubts respecting the behaviour of steel under the influence of fire and water. Another important inquiry requiring a solution, was whether the high-breaking strain of the steel was not obtained at the expense of the ductile properties of the metal. We are enabled to lay before our readers an interesting account of some experiments very lately made in Prussia with a steel boiler in order to ascertain, with some precision, the advantages claimed for the use of steel in the construction of steam generating apparatus.* The particular boiler experimented upon is of the common egg-end shape, without flues; it is 4 Prussian feet in diameter, and is 30 ft. long,† inclusive of the spherical ends. There is a steam dome on the boiler, 2 ft. in diameter and 2 ft. high, as also a man-hole, 15 in. in diameter and 10 in. high. The thickness of the plate is one quarter of an inch thick. There is another boiler built in, parallel to the first one; it is exactly similar in every respect, except that the material of which it is made is simply common iron plate, the thickness of which is 0·414 in. Prussian. Each of the boilers works up to a pressure of 65 lb. The cast-steel boiler, however, was successively tried, by means of the hydraulic test, up to pressures of 98 lb., 130 lb., and at last up to 195 lb., without changing its shape in the least degree, and without showing any leakages. The only exception to this, was that two of the rivets slightly "sweated" under the great pressure of thirteen atmospheres, or 195 lb. After both the boilers were fired in a similar way, day and night, for about six months and a half, and at a pressure of 3½ to 3¾ atmospheres, they were carefully examined, the steel boiler more especially, during the Whitsuntide holidays, while the works were standing. It was then seen that the cast-steel plates were quite unaffected, even at the places most under the influence of the fire. There appeared, on examination, a remarkably small amount of incrustation in the cast-steel boiler, as compared with the boiler of common plate. This was ascribed to the fact that the steel boiler generated 25 per cent. more steam than one of common plate. It had been previously noticed, while the boilers were working, that the relative quantities of water changed into steam, in the steel and iron boiler respectively, were as 5 to 4. The impression produced by the above examination was strengthened after the boiler had been in use for a year and a half. At this subsequent examination, made only very lately, the plates, rivets, and the steam-tight qualities of the cast-steel boiler were in a perfect state, and it did not appear that the least injury had been caused by the fire to the plates more immediately under its influence. The small production of incrustation was confirmed every time the boiler was cleaned; while the incrustation was ⅛ of an inch thick in all the other iron boilers of these works, it was scarcely noticeable in the boiler of cast steel.

During the recent examination, the quantities of feed water were carefully measured by means of Giffard's injector, and the average of twenty days' work, of twelve hours each, gave the quantity of water converted into steam by the cast-steel boiler as equal to 139·92 cubic feet, and by the ordinary iron plate boiler 112·44 cubic feet. The cast-steel boiler thus evaporates 11·66 cubic feet per hour, while the boiler of common plate only steams off 9.37 cubic feet of water per hour. The ratio of the two above numbers (124·44 to 100) is thus almost exactly equal to the ratio of 5 to 4 obtained in the first experiments. During the same time, the quantity of coal consumed was on an average—for the steel boiler, 2,706 lb.; and for the iron boiler, 2,772 lbs., for twelve hours; thus with 1 lb. of coal 3.28 lbs. of water were converted into steam in the steel boiler, and only 2.51 lb. of water in the iron boiler. The steam-generating capabilities of the two boilers were thus as 127.49 to 100. The steaming power of the steel boiler being thereby no less than 28 per cent. higher than that of the other. It must be remarked that the amount of water we have referred to one pound of coal does not represent the *absolute*, but rather the strictly *comparative* evaporating powers of the two boilers, because these boilers are not fired directly, but by means of the waste gases of some puddling furnaces close by. It is also stated that, in several other iron boilers, the worn-out iron plates over the fires were replaced by steel plates, and that these have lasted as long as one and two years, while the previous iron plates were often burnt out within six months.

It is to be regretted that similar experiments to those we have just commented upon, are not oftener undertaken in England. Such experiments, conducted with the requisite scientific precision, are public benefits. The columns of our journal are always open to properly authenticated results of this character. The importance of mild steel as a material for construction needs only to be brought home to our engine and machine manufacturers to ensure its universal adoption; in any case, the prophecy of Mr. Bessemer will not fail to be shortly realized to its fullest extent; and we shall within no lengthened period see steel-plated ships, armed with steel guns and steel shot; furnished with steel boilers generating steam for engines with steel-connecting rods, cranks, and propellers.

[†] One Prussian foot is not quite three-hundredths *less* than a foot English measure.

INSTITUTION OF CIVIL ENGINEERS.

At a meeting of the Institution of Civil Engineers, on the 14th inst.—John R. M'Clean, Esq., vice-president, in the chair—the Paper read was "Description of the Line and Works of the Scinde Railway," by Mr. John Brunton, M.Inst.C.E.

The importance of the valley of the Indus, as the route for commercial as well as for military communication with the Punjaub and the north-west provinces of India, was pointed out by Sir Charles Napier, the Conqueror of Scinde, so far back as the year 1842; and its many natural advantages subsequently attracted the notice of other eminent men. When, therefore, railways were introduced into India, attention was soon drawn to the Indus valley route, having Kurrachee as its sea terminus; and a concession having been granted to Mr. W. P. Andrew, the Scinde Railway Company was formed in 1355. This Company embraced under its management not only the Scinde Railway proper, or the line from Kurrachee to Kotree on the Indus, 108 miles, but also the Punjaub line from Moultan to Lahore and Umritsir, 240 miles, and likewise a flotilla of steamboats for navigating the river from Kotree to Moultan, 570 miles. Within the last three months the Goverment had entrusted to the same Company the construction of a line from Umritsir to Delhi, 280 miles, where a junction would be effected with the nothern terminus of the East Indian Railway. The total length of these four sections was 1,198 miles, but the accounts of each section were kept perfectly distinct.

The construction of the first section of this line, from Kurrachee to Kotree, which had been graphically described as "the neck of the funnel" of the entire system, formed the subject of this communication. After alluding to the works in progress for increasing the depth of water over the bar at the mouth of the harbour of Kurrachee, which was not only the natural port of Scinde, but also of the Punjaub and of Central Asia, and for extending the quay and wharf accommodation, reference was made to statistical returns, showing the rapid increase which had taken place in the import and export trade of the port during the last quarter of a century. Hitherto all commercial communication with the upper distaicts had been carried on by native boats on the Indus, or by caffilahs of camels—no roads worthy of the name existing. This led to great expense, inconvenience, and irregularity. The works of the Scinde Railway were commenced on the 29th of April, 1858, their execution having been originally let to Messrs. James and Edwin Bray, contractors; but since June, 1859, the works had been executed departmentally, without the intervention of a large contractor, by the Company's engineers and inspectors, who had thus favourable opportunities for becoming acquainted with the capabilities of the various classes of natives, as well as for ascertaining the cost of each description of work.

This mode of carrying on the works was forced upon the Company, by the peculiar exigencies of the case; but the Author thought, that for the construction of large works in India, under Government guarantee, the employment of a substantial contractor was a preferable plan. To secure the economical execution of the works, a fair tariff of wages was published, and daily payments were guaranteed. This had the effect of collecting a considerable number of labourers. The province of Scinde contained but a sparse population, and the Scindee was naturally indolent and devoid of muscular power, though not deficient in talent. The natives of the neighbouring state of Cutch were a much superior race, and from thence came a large proportion of the skilled workmen, such as carpenters, masons, smiths, and other handicraftsmen. From the hill tribes of Beloochistan and Affghanistan a hardy race of labourers was obtained. To maintain discipline amongst this body of men, it was found advisable to organize a regular railway police force; and to facilitate the administration of justice, a special magistrate was appointed by the Government. Owing to these precautions very few outrages of a serious charater had occurred. As the line of railway lay at a distance from existing towns and villages, it became necessary to make such arrangements for the feeding, shelter, and health of the different employés as policy no less than humanity suggested. The natives worked in gangs under a self-elected muccadum, or ganger, who made all agreements for work, received the earnings for division, and was himself paid a small per centage by the men. When work was executed by day labour, it was found that its economical execution depended entirely upon the energy and honesty of the muccadum, or native overseer. These qualities were so rare, that piece work had to be resorted to, though it was with difficulty that this was established as a rule. The average prices paid for earth and rock work per cubic yard were—alluvial earth excavated from side trenches and placed in embankment, 4.09 pence; firmly set gravel, or soft shaly material, 4.9 pence; rock requiring bars, but not blasting, 1s. 9d.; and hard rock requiring blasting, the powder, drills, &c., being found by the Company, 2s. Gravel ballast cost 1s. and broken stone ballast 1s. 10d. per cubic yard. The average prices of the principal kinds of work, including the cost of the provisional staff of superintendents, but exclusive of that of the permanent engineering staff, were as follows:—

Earthwork in embankments......	0s.	11½d.	per cubic yard
„ in cuttings, a large portion rock of different degrees of hardness	1s.	6¾d.	„
„ in diversion of roads and streams	0s.	8½d.	„
Pitching slopes	2s.	0d.	per square yard
Masonry, concrete........................	4s.	6d.	per cubic yard
„ dry rubble	3s.	0d.	„
„ common rubble	12s.	0d.	„
„ coursed rubble, with rubble backing	15s.	0d.	„
„ coursed rubble............	20s.	0d.	„
„ block in course	31s.	6d.	„
„ ashlar	1s.	7½d.	per cubic foot
Ballast..........................	1s.	6d.	per cubic yard
Leading and laying permanent way	6s.	0d.	per lineal yard
Fence walling..........................	3s.	0d.	„

The province of Scinde being situated in what was termed the rainless zone, the rainfall was very small, the average quantity measured at Kurrachee during the five years ending 31st August, 1860, amounting only to 5·32 inches per annum. Except during the rainy season, the river beds were dry, but in them water could generally be obtained, by sinking to depths varying from 5 ft. to 30 ft. All the water, however, procured from these wells was more or less saline. In neighbourhood of Kurrachee, the principal features of the country were low hills varying from 150 ft. to 200 ft. in height, consisting of a coarse-grained arenaceous rock, of a dirty yellow colour, abounding with fossils. Most of these hills were capped with conglomerate, more or less disintegrated on the surface. The hills lying north of the Indus to the foot of the Hala range, of which they were spurs, exhibited the effect of great disturbance, and the drainage of the country passed through the fissures thus formed. One of the most remarkable of these was at Dharwat, where during the rains the water of the Bahrun rose at times 70 ft., rushing through the pass with overwhelming force. The Kheytriani hills were composed of pale arenaceous limestone, and those in the neighbourhood of the Rhodh river of calcined clays of various colours.

The distance between Kurrachee and Kotree traversed by the Scinde Railway was 108 miles 10 chains. Of this, 32 miles 50 chains were level, and 75 miles 40 chains were on inclines more or less favourable—1 in 200 being the ruling gradient. The total length of straight line was 74 miles 22 chains; the length of the line on curves was therefore 33 miles 68 chains, the sharpest curve having a radius of 43 chains for 76 chains. The earthworks were generally executed to accommodate a single line of railway, but all the bridges, culverts, and stone viaducts were constructed to carry two lines. In the case of wrought-iron viaducts, the stone piers were adapted to support girders for a double line, while those required for a single way only were erected. Between the workshops at Ghizree junction and the terminus at Bunder head, a distance of 3 miles 15 chains, the line was double; and a short branch, 3½ miles in length, had been constructed from the workshops to the eastern delta of the Indus. The permanent way consisted of the ordinary double-headed rail, fixed in chairs, laid on transverse wooden sleepers. A large proportion of the sleepers were of yellow pine creosoted, sent from England. It was intended to complete the required quantity with sleepers of deodar timber, from the Himalayas; but the native merchant having been unable to fulfil the contract, a supply was purchased of Australian blue and white gum, and native red eyne sleepers. Their respective costs were, creosoted yellow pine 8s. 11d., Australian blue gum 8s., and eyne 7s. 9d. each, delivered in Kurrachee; that of deodar delivered in Kotree being 6s. each. The deodar sleepers were at first steeped in a solution of sulphate of copper, to protect them from the attacks of the white ant, but a Burnetizing apparatus had since been erected at Kotree, where the cost of applying the process only amounted to fivepence halfpenny per sleeper. The result of the Author's experience was, that creosoted yellow pine sleepers split and twist to a great extent, owing to the extreme dryness of the climate, and that they become very brittle. The majority of the fencing consisted of a dry rubble-stone wall, having a coping of stones on edge, set in mortar. Locomotive erecting and repairing shops had been built where the Ghizree branch left the main line. The organization of these works, with a view to their ultimate utility, and at the same time having regard to economy, was surrounded with many difficulties. To employ entirely European workmen would have involved enormous cost. It therefore became necessary to call in the aid of native carpenters and smiths, as far as practicable. They first had to be induced to stand to their work, and then to be taught the use of European tools. This had been accomplished by degrees, and the result had been most satisfactory; the carriages now framed and erected at these shops by Cutch carpenters displaying admirable workmanship. To keep up a supply of European foremen, fitters, engine-erecters, and engine-drivers, the system of taking the sons of European soldiers and clerks as apprentices had been adopted, by which a staff of men thoroughly acclimatized was being educated in all branches of railway mechanism. The electric telegraph with two lines of wires, carried upon posts of deodar, let into cast-iron sockets, was laid along the railway. The block system of working the trains was employed; the needle-speaking instruments being used for conveying information between the station and passing places.

As the line crossed the natural drainage of a great extent of country, a large provision for waterway was necessary. It was comparatively easy to fix the spans of the bridges at the rivers and nullahs, but in crossing wide flat plains the question was difficult. The plain at Pipri was nearly 5 miles broad. Originally, a number of culverts was built there, and catchwater drains were cut, to conduct the rain into the river Guggur. In 1861 the rain was very heavy for six hours in this locality, and the water was ponded up by the embankment, which was soon breached in several places. The line was then lowered to the natural surface of the ground, being in fact laid in a ditch, 16 ft. wide and 2 ft. deep; and during the unusually heavy rains of 1862, the water flowed over the rails to the depth of 9 in., without either damaging the line, or stopping the traffic. Whenever the height of the embankments would admit of it, and to secure the largest amount of waterway, the culverts had a span of 8 ft. 6 in., the permanent way being caried in such cases upon teak timber beams, which supported a platform of planks, covered with ballast, as a protection from fire. The heaviest piece of masonry upon the line was the large stone viaduct across the the Bahrun river. It was 1728 ft. in length, and its greatest height was 31 ft. 6 in. The superficial measurement of the bridged area was 44,064 square feet. It consisted of thirty-two arches, each 46 ft. span, and having a rise of 10 ft. 6 in. Its total cost was £27,185. This viaduct was completed in twenty-two months and a half. There were six viaducts with iron girders, on Warren's principle, of 80 ft. span each, the total number of these spans being forty-two. From experience the author could not speak favourably of these girders, when contrasted with the plate girder, as there was an amount of vibration, both laterally and vertically, caused by passing trains, which had the effect of breaking or loosening the bolts and fixing the longitudinal timber stringers to the cross girders. The viaduct across the Chinnee creek would consist of ten openings, each of 100 ft., spanned by girders of plate iron, of elliptic form in elevation.

The extension of railway communications into wild and uncivilized countries demanded from all grades of the employés the exercise of more than ordinary observation, self-discipline, and energy. It would therefore be wise policy on the part of all foreign railway compaines, and the contractors for the works, to be more strict than they had hitherto been, in ascertaining that the agents sent out from this country at great cost, were something more than proficient in the practical details of there profession as they ought also to be possessed of gentlemanly feelings and habits, by which alone the respect of the uncivilized native could be obtained, and his services secured, so as to reduce the cost of the work, and convert the railway engineer into a pioneer of civilization and a missionary of science.

At the Monthly Ballot the following candidates were balloted for and duly elected:—Messrs. W. D. Dent, M.A., J. Fogerty, J. Lewis, G. W. Rendel, and T. C. Townsend, as Members; Messrs. H. W. F. Bolckow, H. Bolden, O. Bowen, C. W. R. Chapman, J. Davis, C. Gott, C. T. Hargrave, C. Löwinger, R. C. Rapier, and A. Rumball, as Associates.

INSTITUTION OF NAVAL ARCHITECTS.

Having in preceding numbers given abstracts of the principal Papers read before the Institution on the first day, we now proceed to give abstracts of some of the Papers read on the second day of the meeting. The first Paper read on the second day was "On Experiments at Sea with a Rotary Ship-Clinometer," by Professor C. Piazzi Smyth, Astronomer-Royal for Scotland. This instrument, the author said, is based on the principle of free rotation, of which the gyroscope is a well-known example, and is of a differential character only. It has, therefore, no power of determining absolute inclinations or angular position with reference to horizon or meridian, but gives only the successive differences of position which may occur during a limited period of observation. In so far it is inferior to plumb-bobs, levels, fluid surfaces, and all things depending on gravitation for their zero points, but it is superior to them in two points:—1. It is capable of measuring deviations of angular position in every plane, azimuthal as well as vertical; to which latter, gravitational instruments are confined.—2. It is entirely uninfluenced by any of those motions of translation which, either continuous or frequently reversed, are perpetually taking place in every ship at sea, and are of a nature to mix up with the simple clinometrical movements of all gravitional instruments and destroy their value for any exact reference. If, then, this instrument can be produced in a practical form, it can hardly fail to yield valuable and peculiar results when applied to the measurement of the rolling, pitching, and yawing of ships at sea—all of these movements being fully amenable to a difference measuring instrument, and to no other. The author described in detail the construction of the instrument, and then its adjustment and use, stating that, if the instrument be carefully balanced, it will not require further adjustment for a month. In using the instrument, he found that the real difficulty lies chiefly in the complex nature of the phenomena to be observed, viz.:—the angular motions of a ship at sea, which are nothing less than the motions of a pendulum suffering such a continual state of multifarious disturbance that it never makes two successive vibrations exactly alike, but often exceedingly different. The author then showed that, in a case which he tried on board the "Edinburgh," in the Baltic, on the 27th of July, 1859, the mean angular value of a roll was 2·7 deg, and the mean period five seconds; the number of rolls from which this mean was obtained being twenty-one, and the author found it most expedient to compress the results of his observation into these forms, viz.:—to give from the mean of twenty or more observations the average period in seconds of time and the amount in degrees of either a "roll," or a "pitch," or a "yaw" of the ship, as each of them might be observed one after the other, and thereby established the character of the sea, or the movements of the ship upon it for that particular time. On the occasion above-mentioned, when the period of a roll was found to be five seconds, and its amount 2·7 deg., the period of a "pitch" was found to be eight seconds, and the amount 0·6 deg., the motion of the ship being described as "gentle and pleasant" to the feelings. But the movements had been described as decidedly disagreeable on a previous occasion where a roll had a period of four seconds with an amount of 5·5 deg., and a "pitch" a period of three seconds only, with an amount of 2·7 deg. The latter was a case of crossing the North Sea, against an easterly ground swell, and with a N.E. wind on the beam; while in the former case they were going free before a west wind. This mode of registration, even in these simple average particulars, told a great deal. The author concluded by stating that there is much more in the movements of the sea than average particulars will always bring out, and gave tables showing that a series of individual observations sometimes brought to light the existence of extensive undulations of a long period; and showing also the sensibility of the rotary ship clinometer, and the very complicated nature of the phenomena which it is required to observe. The Paper contained tables of results of observations acquired on the voyage above mentioned.

The next Paper read was "On the Rolling of Ships as influenced by their Forms and by the Disposition of their Weights," by J. Scott Russell, Esq., F.R.S., Vice-President, I.N.A.

The author stated that Professor Woolley, at the opening of the Institution, had in an admirable Paper laid before them with judicial impartiality, the condition of the science of Naval Architecture, and had mentioned the strong points and the weak points of their knowledge, in order to direct their attention to the adoption of established truths, and their immediate application to their designs of ships, and also to diligent research in those regions of inquiry where exact principles were still wanting. Among the points which had been established as matters of science, but not commonly used in professional practice, he pointed out the whole of the questions affecting the stability of ships, their power to carry top-weight, and pressure of sail in smooth water, and in a state of rest; he mentioned the questions relating to motion of ships, of the resistance of ships when propelled through smooth water, and of the behaviour of ships in troubled water, as questions to a great degree unsolved. The author was sure that it must be gratifying to Professor Woolley to find that the impulse he gave had not been thrown away on members of the Institution, but had been responded to by three valuable Papers—one by Mr. Froude, one by Mr. Crossland, and one by Professor Rankine. The author then said he had taken to himself the investigation of the following narrow question:—What were the forms, proportions, and distribution of weights which a naval architect would adopt, in the present state of their knowledge of that question, as likely to give to a ship the best behaviour in a sea-way—taking into consideration the peculiar circumstances for which the ship might be designed? It was necessary, he said, at the outset of the inquiry, to ascertain what qualities in the behaviour of a ship they wanted to find; for if ease were to be the one thing, they had only to search in a certain direction, and he thought they knew where to find it. But there were quite other qualities they might have to search for; easy rolling was good, but limited rolling was in some instances much more important, as was especially the case in a man-of-war, where it was desirable to keep the gun platform as nearly level as possible. He proposed to seek out from the knowledge which had been contributed upon that subject, what recommendations they might safely adopt or reject. There were two problems to be solved of a very different nature, depending upon whether an easy movement be required, or a stable platform; but there were certain circumstances common to both in regard to which he would state certain definite conclusions. He then dwelt upon the uneasy, lifting motion occasioned by the injudicious form of the ship at the water-line, and which form was such that great difference existed between the immersed and emersed portions of the sides of the vessel when rolling; and he spoke also of the flare-out bow as being a form of bow having no advantages, but rather serving to give the ship an accumulation of vertical motion when pitching a and scending, and a series of violent concussions with the waves. The first condition, then, of course, would be that the body of the ship should be so formed that at the water-line there should be no flare-out above the water, or rapid falling away under the water; and that could be accomplished by making the surfaces of the ship between wind and water nearly vertical. He would go a little further, and adopt a tumble-home line as far as he could along the middle of the ship, and he approved of as much tumble-home at the bow, in a large vessel, as could be conveniently introduced. Having supposed all bad forms to be removed from a ship, so that all the parts near the surface of the water could rise out of it and go into it again quite easily, the next question was, what further should they wish to obtain in regard to the movement of a ship on the waves? Did they wish her to rise and fall, to roll and right herself in a lively manner with every undulation of the sea, never taking in the water, but, as it is called, swimming like a duck? That was a kind of movement desirable for some purposes, and he would call it the quality of rolling with the sea, and would carefully examine it. The rolling with the sea was to be obtained by great breadth, little draught of water, and extreme lightness with a large buoyant out-of-water body. He found it convenient in analysing the properties of a ship, to use the phrases "out-of-water body," "under-water body," and "shoulders;" by the under-water body, meaning the part which in rolling does not come out of the water; the shoulders, meaning those parts which are commonly called wedges of immersion and emersion, or the parts of a ship between wind and water; and the out-of-water body, meaning that which rises above the shoulders. He comprehended in the shoulders 14 deg. above and below the water, a size which laid a depth of side under the water equal to one-eighth of the beam of the ship, and which raised a like proportion out of the water. He next treated of the faults of such a vessel as the one above referred to: showing that it was not calculated for carrying heavy weights, or for holding on a wind, or for the general purposes of a ship; and that it was in fact a barge, fast to fly before the wind, and wholesome to go on shallow water or through breakers; but the great danger to a ship, all shoulder, and no under-water body, was that across a sharp and breaking sea she was liable to capsize; for, when the sea broke, the front and back of the wave became nearly perpendicular, the shallow vessel took, of course, the position of the surface of the water, and having taken it on the face of the wave, she would retain it on the back of the wave, so that what was the top before would become the place of the bottom now, or, in other words, she would be turned over. This, he said, was the extreme result of extreme liveliness; for all other cases, liveliness seemed safety. The rolling with the wave, he said, was accomplished in a high degree by a plank floating on the water. He next took a vessel of the *extreme other sort*; and that he would represent by a vertical plank floating upright, and kept in that position merely by having its centre of gravity slightly below its centre of buoyancy; it then remained to consider what were the movements to which in the course of wave motion it would have to submit. He observed that this question was a more complicated one, and stated that during every wave the water performed both a vertical and horizontal oscillation. Its greatest motion forward was at the top of the wave, its greatest motion backwards was at the bottom of the wave, its greatest motion upwards was at mid-height on the rising wave, and its greatest motion downwards was at mid-height on the descending wave. From this it was to be gathered that a floating body standing upright in the water was violently pushed forward during one-half of the motion, backwards during the other half, and upwards and downwards. Moreover, it was proved and admitted that those motions were performed circular-wise, and that each point in the water, and each point in the float, moved in a circular path, and its revolution was perfectly uniform. But the circular path of a body floating on the surface of the water was, unhappily, very different from the circular path of a body immersed below the surface; and after showing by diagrams the effects these conditions had upon the two planks, and explaining the causes of various phenomena presented, he stated that the practical use to be made of such conditions was, that if the naval architect made his ship all flotation at the surface, he must combine with it a deep vertical body; and it might be so proportioned that the forces acting on the one to produce oscillation one way might nearly balance the forces tending to produce oscillation the other way, and between the two the vessel would be saved from rolling. He then went on to say that great capacity and carrying power might be had in the midship portion of the vessel, without her following the surface water, if care were taken to give her a long, vertical line of bow, and a sharp, deep deadwood; and thus the evils arising from surface oscillation might be remedied by using the peculiarities of deep water oscillation. The author next considered how far the disposition of the weights in the interior of a ship affected her stability and rolling; and, first, he questioned the wisdom of lessening her stability under canvas for the purpose of giving her a longer periodic time of roll, and he did so after having carefully examined the subject, and compared the principle with a long course of practice. Having treated of two different kinds of stability—one being due to the form of the vessel, and the other being due to weights placed within her—he said that, to understand them apart from each other, the centre of gravity must be placed where it could have no action on stability, which was in the axis of motion, or in the centre of the water-line of such a ship as he was then going to describe. He supposed a ship to be inclined by any two forces; they had the part under water divided into two—a symmetrical body and an unsymmetrical body—the former part always under water, the latter placed under water or taken out of it as the ship inclined to either side; the one he would call the under-water body, the other he would call the shoulder. In reference to stability, one tended to upright the ship, the other tended to overset her; the resultant of these two forces determined the stability or instability of the ship. The momentum of that resultant force measured her power to resist overturning, whether from force of sail or any other force. The distance of that resultant from the axis of the ship was one measure of her stability; because, in that case, the height of the meta-centre above the water-line measured the stability of the ship arising from form and bulk merely, or, as he had said, it was the stability of form. He would next treat of that kind of stability which arose from weight; and for that purpose would, first, raise the centre of gravity above the axis of rotation, so as to get the action of the top weight. Such a condition counteracted the righting power of the shoulder, and tended to overturn the ship; and in proportion as he raised the weight, he counteracted the stability which arose from form, and when he had reached the height of the meta-centre he had entirely neutralized it. It was necessary, he said, to discriminate between these cases for the future; what was called a measure of stability, was more properly a measure of spare stability, or stability still to be disposed of. He would call the measure of stability of form, the absolute height of the meta-centre above the water-line; the height of the centre of weight above the water-line would be measured by the height of the centre of gravity above the same line; and the remaining height left between the centre of gravity and the meta-centre, would be the just measure of the surplus stability still to be disposed of. He then proceeded to show the errors which arose from confusing the terms; and that it was possible for vessels having the same interval of distance between the meta-centre and the centre of gaavity to have a totally different behaviour in a sea-way; and from his own investigations, he said, he should adopt very different maxims from those which Mr. Froude had arrived at. First, he should not deem it expedient to design a ship with a high meta-centric height out of water, and a high centre of gravity, for the purpose of diminishing the velocity of oscillation; second, he would not design a vessel with weights placed high, nor at a great distance from the axis of revolution, for that purpose; third, he would endeavour to diminish the extent and violence of rolling motion in the design of a new ship by diminishing the total meta-centric height above the axis of rotation, and by that means seek to diminish the forces by which the water acts to cause rolling; fourth, the absolute meta-centric height in a good form of ship might be greatly reduced —even to the level of the water at the load-water-line; fifth, the extent to which the place of the centre of weight of the ship and cargo migh be lowered easily, must depend mainly upon the purposes of the ship; but with a low place of meta-centre, and a lower place of centre of gravity, preserving between them only the interval required for carrying sail, all the injurious movements and stresses which injure and endanger a ship would be a minimum, and all the forces tending to produce oscillation being reduced to a minimum in total quantity, they would have the least need of strength and force.

The next Paper read was "On Isochronism of Oscillation in Floating Bodies," by W. Froude, Esq., Assoc.I.N.A. The following is an abstract of it;—

The equations of motion for a ship rolling in a sea-way, as given by Mr. Froude in his Paper, *Trans. I.N.A.*, 1861, were rigorously applicable only to a ship which would perform isochronous oscillations in still water, and objections had been expressed to this condition as impairing the practical value of the equation by too greatly limiting the range of its fair application. It was therefore worth while to inquire how far ships of any ordinary type were likely to deviate from isochronism, and what specialty of form isochronism implied. The answer would arise out of a comparison between the *vis viva* embodied in the oscillatory motions of ships of various forms, and the dynamic stability out of the discharge of which the *vis viva* was generated in the course of each oscillation. The statical moment of stability due to the inclination of a given stable floating body was well known to be wholly expressible in terms of two equal vertical resultant—sone, ship's weight acting downwards through the ship's centre of gravity; the other, her flotation acting upwards through the centre of buoyancy—their combined action forming a "couple" whose span is the horizontal interval between them. Thus no horizontal motion could be impressed on the ship's centre of gravity from the mere operation of these forces; nor could any such motion arise in the course of oscillation except for the secondary or deviation forces involved in the quasi-wave motion impressed on the volumes of water contiguous to the ship in the course of her oscillations. And as this exception could not be serious, and was probably trifling in amount, it remained that practically the whole movement of an oscillating ship might be expressed in terms of an angular motion *round* her centre of gravity, and the *vis viva* embodied in each of these motions would be as the square of its velocity. In the former, it would be the "moment of inertia" of the ship's mass measured on her "radius of gyration;" in the latter, it would depend on the form of the ship; but even in the most extravagant Symondite, its ratio to the "moment of inertia" would scarcely be greater than that of $M_2\theta^2$ to ρ^2, (M being the height of the meta-centre above the centre of gravity, θ the angle of inclination, and ρ the radius of gyration), and even with $\theta = 60$ deg. this could scarcely exceed 1-64th. Now since, *cæteris paribus*, the time occupied in performing work is as the square root of the amount of work, the addition of 1-64th to the work will only enlarge the time occupied in the performance by about 1-128th; so that practically, we may extend to large angles the proposition usually limited to small ones, that the work to be performed in the oscillation of a ship is measured by her moment of inertia round her centre of gravity. Hence, Chapman's view, that a ship suspended by her meta-centre would oscillate in the same period as if afloat, errs in the ratio of her radius of gyration when so suspended to her radius of gyration round her centre of gravity; practically, the former would seldom exceed the latter by more than 10 or 12 per cent. If, however, the point on which the meta-centre hangs, be itself free to take lateral motion (as when if it be the end of a long line suspended from a great height), the oscillation will be performed round the centre of gravity (which will undergo also a small vertical motion), the conditions will be almost identical with those of the ship as afloat, and the period of oscillation will be in each case the same. And if a similar mode of suspension be applied to the plane on which, in a well-known proposition, the ship is supposed to oscillate like a rocking-chair, the range of the proposition may be extended to any meta-centric involute, since all horizontal motions involved in the action may thus be eliminated. If the figure of the ship be such that her meta-centre when upright is also her meta-centre for all inclinations, she will have the same relation to an isochronous ship, which the ordinary pendulum bears to a cycloidal pendulum; and the enlargement of her periodic time up to an angle of 50 deg. or 60 deg., may be sufficiently expressed by a ratio involving a single term of the appropriate series, and which is equivalent to (1 ÷ 1-8th vers θ): at 60 deg. this would be only 1 + 1-16th. The form of ship which involves isochronism is that in which the moment of stability is as the angle of inclination; and the question as to what form involves this law, or any other particular law, can only be answered relatively. Given the form of the immersed body, what must be the corresponding form of the superstructure? If we express the form of the whole ship by an equivalent midship section, the primary type of the form which has an unchanging meta-centre is circular, but the same result is secured if throughout all inclinations the immergent and emergent surfaces form the same angle (the one tending inwards, the other outwards, or *vice versa*) with the line flotation; and this construction involves the condition that the breadth at the line of flotation (or what is equivalent, the moment of inertia of the plane of flotation) is the same for all angles. From a ship thus figured, an isochronous ship may be at once derived with a high degree of approximation, by lengthening in each case the equivalent line or breadth of flotation, in the cube root of the ratio of the arc to the sine of the inclination, since the growth of the moment of stability is as the cube of that line, so that we shall thus approximately work out *mutatis mutandis*, the analogy of the moments of the simple pendulum to those of the cycloidal or isochronous pendulum.

A Paper "On the Comparative Straining Action upon a Ship of different Kinds of Vertical Oscillation," by Professor W. J. Macquorn Rankine, C.E., LL.D., F.R.S., Assoc.I.N.A.:—

The author stated that he was induced to write this Paper by the publication of some remarks in the third volume of the "Transactions" of the Institution, by Mr. Froude, questioning the accuracy of the commonly received opinion, that the vertical oscillation of the centre of gravity, or "bodily rising and falling" of a ship of the form known as the "Symondite," constitutes an "uneasy motion;" that is, as the author understood it, a motion that produces peculiarly severe stress on the structure of the ship. For brevity's sake, he called that kind of oscillation the "dipping motion," because it consisted of an alternate dipping into and rising out of the water. Another kind of vertical oscillation, whose straining effect would compare with that of the "dipping motion," was the vertical component of the motion of the ship when she accompanied bodily the motion of the waves; and this kind of motion he, for brevity's sake, called the "heaving motion." The dipping motion of a "Symondite" ship, said the author, originates in the difference for a given angle of roll, between the "solids of immersion and emersion;" and the extent of that dipping motion, though not necessarily equal to, depends upon, the depth found by dividing that difference by the water-line area. That depth, indeed, is very nearly one-half of the extent of the dipping motion which would be produced by a very sudden roll. If we call the depth found by dividing the displacement by the water-line area the "mean depth of displacement," then half the extent of dip for a very sudden roll is less than the mean depth of displacement, very nearly in the same proportion that the difference between the solids of immersion and of emersion is less than the displacement. This rule he expressed algebraically, and then remarked that the extent of the dipping motion was in every case small as compared with the extent of the heaving motion. In a well-proportioned ship, he continued, the rolling motion is less frequent than the heaving motion, which keeps time with the waves; hence, if the periodic time of the dipping motion were the same with that of the rolling motion (that is, a dip and a rise to each double roll), there could be no doubt of the accuracy of Mr. Froude's conclusion—that the straining effect of the dipping motion is trifling. But the dipping motion has a periodic time of its own, which is always considerably shorter than the periodic time of the rolling motion, and which may be considerably shorter than that of the heaving motion also. It is quite possible, therefore, that the greater frequency of the dipping motion may make up for its less extent, so as to make its straining effect on the ship considerable. It is further to be remarked, said the author, that the possible extent of the dipping motion is not limited to the double of the depth stated previously. That depth is one half of the extent of the dipping motion, which may be set going by a *single sudden roll*, and which, even though the rolling should stop, will be followed by a series of dips of gradually diminishing extent until the motion is stopped by the resistance of the water. When a "Symondite" ship makes a series of rolls, each roll originates a fresh series of dipping oscillations; and should the periodic time of rolling happen to be double, quadruple, or any *even multiple* of the periodic time of dipping, so that each roll coincides with the rising part of the previously existing dipping motion, the extent of the dipping motion may go on continually increasing to an amount limited only by the resistance of the water; just as the extent of the rolling motion of a ship may, as Mr. Froude has shown, go on increasing when its periodic time coincides with that of the waves. The author then proceeded to explain how the several parts of a body are acted upon under different conditions, and showed that when a heavy body, supported in any manner, undergoes a simultaneous and equal variation of the motion of all its particles, as in bodily oscillations of a ship, the straining effect is the same as if the weight of each particle, and of the entire body, were changed into the resultant of that weight and of a force equal and opposite to the force required to produce the varied motion. He next dealt with the motion in question as an isochronous oscillation, and gave a rule, and expressed algebraically in what proportion the change in the resultant reaction of each particle, and of the entire body, is equivalent to an *alternate increase and diminution of the weight*. The *heaving motion* was next considered. Its periodic time, the author stated, is the same with that of a pendulum whose length is to the length of a wave as the radius of a circle to the circumference; and then followed various applications of algebraical formulæ, showing the proportionate stress and comparative straining effect of the two motions; from which it appeared that the straining action of the dipping motion was by no means trifling in comparison with that of the heaving motion produced even by a wave of considerable height; being less only in the ratio of 725 to 1,250, or 4 to 7 nearly. He concluded by saying that the results which he had shown were in accordance with his former statement—that it is possible that the frequency of the dipping motion may make up for the smallness of its extent, so as to make its straining effect considerable; and in conjunction with the possible increase in extent of the dipping motion before described, they confirm the prevalent opinion that the so-called "Symondite" form, which tends to produce dipping oscillation, is a cause of "uneasy" motion, and of undue strain upon the ship.

At the evening meeting, Friday, March 27, 1863—Henry Chatfield, Esq., Vice-President, I.N.A., in the chair—the first Paper read was by Mr. Charles Lamport, Assoc.I.N.A., "On the Construction and Support of Iron and other Masts and Spars." The following is a brief abstract:—

The strength and fitness of the masts and spars of a ship, for the service they had to perform, were elements in the success of the whole sailing machine, as important as the strength and durability of the hull itself. Broadly considered, the last twenty years had not effected any important changes in the masting and sparring of vessels, except such as had arisen from the necessity to supplement the natural deficiencies of the original material, wood; or from the substitution of another material altogether, iron. The introduction of iron and steel in place of wood, for the masts and spars of ships, had opened the whole question to reconsideration. In designing an iron mast, the first, and most obvious point, was to determine the nature and degree of the strain it had to bear, along with the exigencies of its form and application; the second was to arrange the material in quantity and shape so as most effectually to meet that strain; and the third was to modify the relation of the two to the extent that the exigencies of their application would allow to suit the capabilities of the new material. In reference to the first of these heads, the author showed that the normal strain which the mast has to bear is brought upon it as upon a column. Unsupported by the shrouds, no mast can uphold its own weight against the violent motions of a ship at sea. To design an iron mast, with a view to resist the maximum transverse strain brought on it, would be a waste of material. The object should be to answer the demands upon its strength as a column, consistent with lightness, absence of bulk, ease of maintenance and repair, and a provision for cutting away. To secure these, we must give up the idea of taper spars, and of tall masts, "bending like a fishing rod," and imitate rather the human spine, the vertebrate articulations of which, upheld by muscular supports, combine at once columnar strength with easy motion. The mast should not taper, because every particle should be brought as nearly as possible into the direct line of the strain applied; otherwise there will be a tendency to "buckling." The usual plan of wedging should be abandoned with iron masts, because it converts the mast into a beam, in the position least capable of resisting a transverse strain, viz., fixed at one end and loaded at the other. The lower mast, topmast, and top-gallant mast should each be rigid in itself, but yielding with an articulated flexure to the elastic spring of the shrouds and stays. The oscillation of each should be from the keel, and the author therefore applies a cast-iron foot, terminating in a ball a little flattened in the fore and aft direction to prevent the mast twisting and widening above to give a flat, even, but moveable support to the plates of the hollow mast. The flattened ball works in a cast-iron socket or step. The author explained that this construction agreed with the experiments of Hodgkinson, and after further reference to those experiments, and also to Dr. Fairbairn's, stated as the results of calculation, that iron masts, even of ½-inch plates, when uncrippled by wedging, were superior in strength to wooden masts of ordinary dimensions. He next gave an elaborate description of various practical details of construction in reference to masts, top-masts, and yards, recommending a great variety of improvements in those details, and next proceeded to consider the support of masts, &c. The efficient support of the mast of a ship was a question of equal importance with that of the mast's capability to maintain its portion of the duty of propulsion. Considering the masts as pillars, the measure of their support was the measure of their efficiency. The problem for solution was to apply a given amount of support most usefully, under the conditions of working efficiency. Every step in its solution necessitated a compromise. The masts had to be supported laterally, as well as fore and aft. It would be easy by "spreading" the rigging to give a more direct support against the forward pressure of the wind; but what was gained in this direction was lost in the power to withhold the mast against the side pressure. Again, the more complete the support, the more rigid became the system of masts and yards to the loss of a certain storage equalization of force absorbed and given out by their elastic play. That spring, and consequent momentum, should depend upon the elasticity of the shrouds entirely. If they adopt wire rigging they must sacrifice more or less of this advan-

DONKIN'S AXLE BEARINGS.

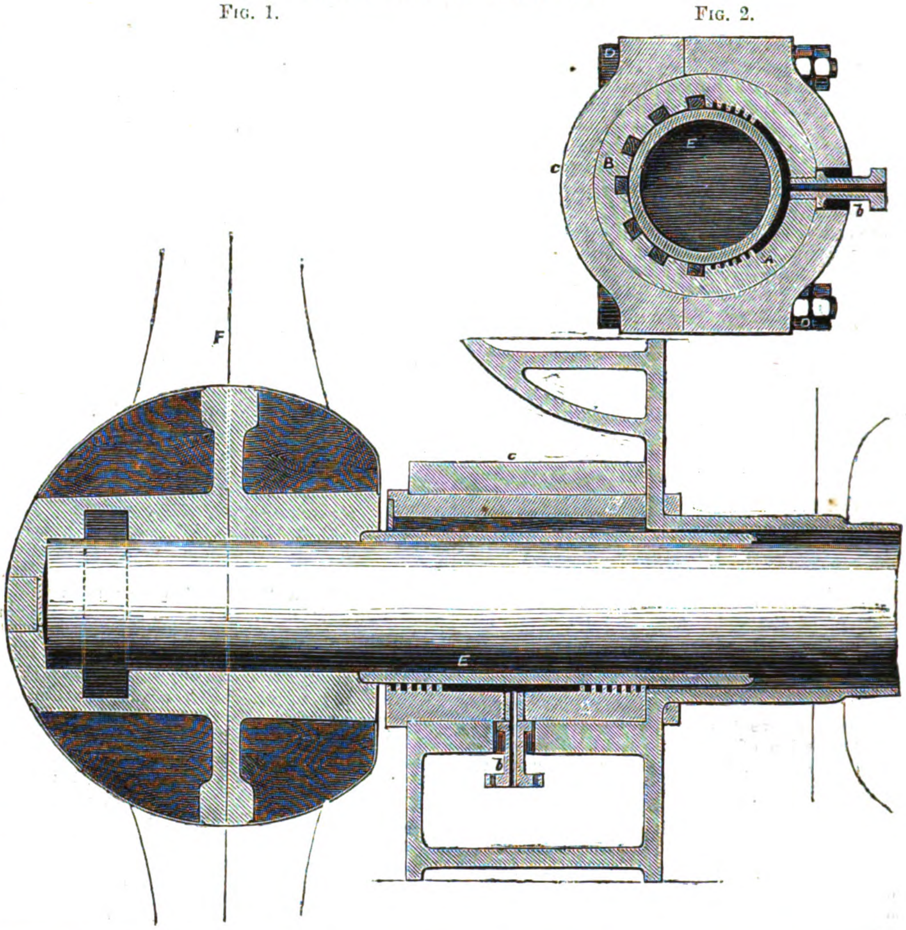

Fig. 1. Fig. 2.

tage. They made a compromise between the lightness and less resistance presented by it to the air, "on a wind," and the play and momentum of the whole system. He advocated the separate attachment of each pair of shrouds at points varying from the cap at the mast-head to the truss hoop of the lower yard. Further, he proposed to combine the advantages of both hemp and wire rigging by the use of the former for the two aftermost shrouds, and of the latter for those whose sustaining power came into play. In conclusion, he said that if proof be deemed indispensable for the anchors and chains of ships, why should the masts and spars be passed over without test? The one class of appliances was as indispensable to the safety of a ship as the other. He thought that a few preliminary experiments, instituted under proper superintendence, with a rule that all variations should be satisfactorily "proved," would very soon supply an amount of information on this subject which would be as interesting as it might prove beneficial to every branch of the shipping interest.

G. C. Mackrow, Esq., Assoc.I.N.A., then read a Paper "On a New Mode of Constructing Iron Bulkheads."

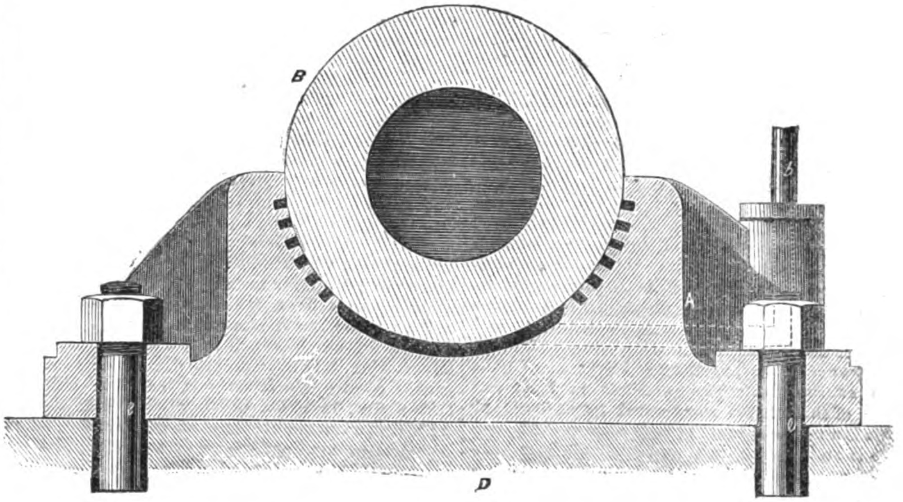
After alluding to the precious freights and living cargoes that vessels have often to carry, the author urged the great importance of water-tight compartments, and hence the desirability of obtaining the most complete and efficient vertical bulkheads with a given amount of material. Reference was made to a sketch showing a bulkhead constructed in the usual manner, with the exception of some slight additional thickness at the middle, and he then stated that, at the wreck of the "Tyne," in the English Channel, some few years back, several of the plates of the engine-room bulkhead had their rivet-heads sheared completely off, and great overlapping of the plates was the result. He next drew attention to a sketch showing his proposed method of construction, the two principal features of which are, 1st—the whole of the bulkhead is worked "flush" or "jump-jointed;" and 2nd, it is supported at the vertical and horizontal joints by T-irons which form at once butt and joint straps and stiffeners—an angle iron being placed between every alternate T-iron to further support and stiffen the structure. He considered the value of such bulkheads in vessels of war to be indisputable, since when a vessels strikes her adversary with her stem, the impact or force of the blow is transmitted to the middle-line bulkhead; and he spoke of the "Minotaur," "Northumberland," and "Agincourt," as having bulkheads in course of construction on a method similar to the one proposed, the chief objection to them, however, being that an increased weight of iron is employed. This the author illustrated by tables showing the quantity, description, and weight of iron necessary for the construction of two bulkheads of the same area, which tables served to show that a saving of about $2\frac{3}{4}$ per cent. would be effected by the adoption of his proposed method. The author next proposed another method of construction by which, too, considerable saving of weight would be effected, the chief point in it being to work the plates vertically instead of horizontally, placing a T-iron at every joint. But he confessed that this method did not in all respects accord with his own notions, so he left the matter to be dealt with by the eminent gentlemen present, who would doubtless point out any real practical objections to the adoption of the plan.

[Mr. W. J. Hay's Paper "On the Fouling of Ships," which followed that read by Mr. Mackrow, appeared in the last number of the Mechanics' Magazine.]

James Watt a Photographer.—A discovery of great historico-scientific interest is said to have been just made. It is alleged in a letter published in a Birmingham contemporary that "distinct evidence has been got to show that James Watt was engaged in photographic experiments, and that he took portraits." This announcement is certainly startling enough, but we are assured that "it is true."

DONKIN'S AXLE BEARINGS.

Fig. 3.



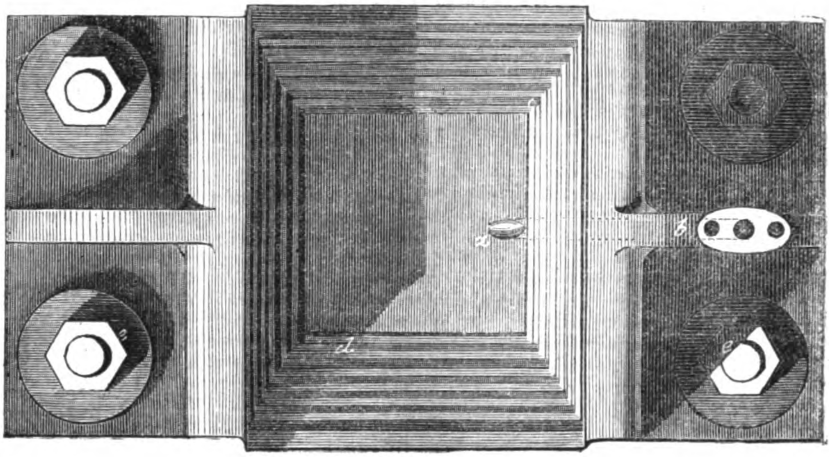


Fig. 4.

DONKIN'S AXLE BEARINGS.

Mr. Bryan Donkin, of Bermondsey, engineer, has recently patented an improvement in bearings for axles and sliding surfaces.

The invention consists in providing a water or liquid bearing for shafts, axles, pivots, and sliding surfaces, by a continuous circulation of liquid forced between a metal box and the shaft, axle, pivot, or sliding surface, so as to prevent contact of surface with surface, whatever be the material constituting such surface.

The box or case is shaped to correspond with the shape of the revolving or sliding surface to be used with it, and form therein a central cavity, followed by several concentric quadrangular or other cells, according to the surface. An orifice is made in the central cavity to allow of the inlet of water or other liquid under pressure.

Fig. 1 of the accompanying engravings shows, in longitudinal section, a water bearing applied as the under bearing for the shaft of a screw propeller. Fig. 2 is a section of fig. 1. A is a metal case, of the form shown in the sectional view, fig. 2. It is formed on the interior with a central cavity, into which water is admitted under pressure through a pipe *b* connected with a force pump. *c, c* are quadrangular cells, more clearly shown at figs. 3 and 4, extending upwards from the central cavity to the sides and ends of the case. *d, d* are walls or partitions between the cells. These walls or partitions may be made of lignum vitæ, so as to resemble the present system of supporting screw propeller shafts, and thus allow of a certain portion of the weight, if necessary, being borne by the bearing. Passages are formed in the partitions at both ends of the case. These passages are not carried in the same line, but are made to break joint. They are also gradually reduced in width from the central cavity outwards. B is the upper bearing, lined with blocks of lignum vitæ or other hard wood, and constructed in the usual manner. The upper and lower bearings are surrounded by hoops or straps C C, secured together by bolts and nuts D D. E is the screw propeller shaft, and F the screw. The weight of the shaft and screw being ascertained, water, under a pressure sufficient to overcome the whole or part of that weight, is forced through the inlet pipe into the central cavity, from which it circulates through the cells one after the other, slightly raising the shaft and interposing a film of water between it and the interior of the case, and finally escaping in thin sheets from the ends and sides of the case. In adjusting the upper bearing, allowance must be made for the raising of the shaft in the lower bearing, as above explained.

Fig. 3 is a cross section of a rolling mill fly-wheel shaft and of a water bearing for the same. Fig. 4 is a plan of the bearing. A is the case, *a* the central cavity, *b* the pipe for the admission of water, *c, c* the cells, *d, d* the walls between the cells, the passages through the walls of the cells are not shown. B is the fly-wheel shaft, and *e, e* bolts and nuts for securing the case A to the foundation D. The upper bearing is dispensed with, the weight of the shaft and parts connected with it being sufficient to keep it in its place.

According to the shape of the surface to which the bearing is to be applied, so must its shape be altered. For instance, if the surface be flat, so must the interior of the case with the central and cellular compartments be flat also. The walls of the cells may be made of lignum vitæ, or other hard wood, letinto the case, so that, in the event of the pressure of water failing, the shaft might revolve upon the wood.

LONDON FIRES.

Probably most of our readers remember that the Mechanics' Magazine for a great many years inserted annually Mr. Baddeley's report on London Fires. At last the report grew to such dimensions that we were unable to find space for it in our columns. Besides, it was considered by some to be scarcely suitable to a work devoted to engineering progress. The document on London Fires in 1862 will be found in this week's *Building News*—a journal devoted both to the production and preservation of buildings. It contains the usual analysis of the causes, character, and results of the fires in London during 1862.

The report says that the total number of calls given at the fire-engine stations in 1862 was 1,543; of these 1,303 were put down as fires, 129 were chimney fires, and 111 false alarms. Although there is an increase in the number of fires, and some few of them have been of considerable magnitude, it is gratifying to know that, upon the whole, a considerable amelioration has taken place in the character of these calamities during the past year. The number of fires, 1,303, is an increase of 120 upon the previous year, and an increase of 497 upon the average of the last twenty-nine years. This increase is, however, more apparent than real, arising, in a great measure, from the number of trifling accidents, which are now put down as "fires," that used formerly to be called "false alarms."

The number of fires at which the premises were totally destroyed is said to be 33; seriously damaged, 288; and slightly damaged, 982. This classification, which is wholly arbitrary, gives but a very imperfect idea of the real character of the fires; an approximate estimate has, therefore, been made of the damage done at each, by which it appears that the number of fires at which the damage done was merely nominal, or

Of these fires, 354 were extinguished by the inmates themselves, 366 by the inmates with casual assistance, 569 were extinguished by the the firemen, and 14 were self-extinguished. Upon 45 occasions the inmates themselves applied for the firemen's aid, in 315 cases the first call was given by the police, and in 912 cases by strangers. Upon 31 occasions the firemen were summoned to fires in outlying districts by means of the eelectric telegraph.

A glance at the foregoing facts will make it evident that the majority of last year's fires in the metropolis were of a very insignificant character.

After giving an account of the distribution of fires during 1862, buildings insured and uninsured, and the occupancy of the premises in which the fires occurred, the report says there is scarcely any circumstance connected with fires more interesting, or more instructive, than their *causes*. It is now nearly twenty years since I drew attention to the small amount of care that was given to this subject by the fire-brigade. It is quite true that the origin of fires is often involved in considerable obscurity, and requires more ability for its unravelment than falls to the lot of those upon whom this duty devolves; their superficial method of investigation seldom penetrating far enough to probe out deeply-hidden causes. The systematic regulations of the fire-establishment often necessitate the reporting of fires before the cause can possibly be ascertained; accordingly, it is put down as unknown, and there the matter ends. In the annual report of the Superintendent of the Fire Brigade for last year, no less than 493 fires are put down to *unknown* causes. Under the head of doubtful 10, and incendiarism 3, are included all the wilful fires of the year. A very slight knowledge of the subject will suffice to show the inaccuracy of these returns. Impossible causes of fire are frequently reported; thus, in December last, a fire was said to be caused by the ignition of *nitric acid* by *friction*. Another fire, only an hour previous, was reported, cause *unknown*, the damage done being "four cases of *nitric acid* taking fire and being destroyed, and several others damaged." Both fires occurred in the street, in the waggons of Messrs. Pickford and Co., the well-known carriers.

Much care has been bestowed upon the following analysis, which (although far from perfect) gives the proximate causes of a large proportion of last year's fires, which, it will be seen, are much of the usual character; bearing out the remark of Dr. Winter, in his "Curiosities of Civilization," that, "among the more common causes of fire (such as gas, candles, curtains taking fire, children playing with fire, stoves, &c.), it is remarkable how uniformly the same proportions obtain from year to year. We are informed by the Post Office authorities, that about eight persons daily drop their letters into the post without directing them—we know that there is an unvarying per centage of broken heads and limbs received into the hospitals—and here we see that a regular number of houses take fire, year by year, from the leaping out of a spark, or the dropping of smouldering tobacco."

It may, perhaps, excite some surprise, to find how many fires are attributable to the last-named cause. The greater number of these fires occur in the tap-room, in the skittle-ground, or before the bar of publichouses and beer-shops. The remains of a pipe of tobacco, the end of a cigar, or an unextinguished fusee thrown carelessly into the street, is frequently blown down an area, or into the basement of buildings, where, meeting with combustible matters, a conflagration is commenced. In the greater number of such instances the damage done is trifling; sometimes, however, it is otherwise, and two of the largest and most destructive fires of 1862 originated in skittle-grounds from unextinguished tobacco. The most painful part of the subject is the very large number of fires that are well known to have been wilfully occasioned, as well as those that have been suspicious in their origin, and the very few instances in which the perpetrators have been brought to justice. It must be confessed there is a delicacy on the part of the fire-offices, touching this question, which is most mischievous. At the same time, it is well-known that when a fire-office resists a claim they know to be fraudulent (even if the fire cannot be proved to be wilful), they receive but scant justice at the hands of juries. I have heard this accounted for on the ground of sympathy; that it was so difficult to find a jury of which at least one member had not had a fire! The crime of incendiarism is most frequently associated with others; and during the past year more than one well-known incendiary has received his deserts at the hand of justice for other villanies committed by him. Under a well-organized system of fire-police, it is probable that the greater number of incendiary fires would be nipped in the bud, the offenders fearlessly grappled with, and such crimes become almost as scarce in London as they now are in Gravesend, where but a few years since they were so rife. Prompt discovery and early extinction of the fire is fatal to the scheme, and often leads to the detection of the incendiary.

Considering the extensive use of lucifer-matches, it might have been supposed that a larger number of fires would have been traced to their agency. There is good reason to believe that many of the *unknown* fires have originated from the accidental ignition of these matches. Such accidents are preventible. Messrs. Bryant and May have produced a match which is ignitable only by a properly prepared surface, and are therefore not liable to accidental or spontaneous ignition. These matches have the further advantage of containing no phosphorus or poisonous materials, and do not give out any sulphurous or unpleasant odour. They are but of little more expense than the ordinary lucifer matches, and are much esteemed by careful housekeepers.

Mr. Baddeley concludes his very able report with the following comments:—The public are anxiously looking for the production of the Government plan for affording to the metropolis increased protection from fire. This natural anxiety has been by no means lessened, by the ambiguous and unsatisfactory answer recently given to Mr. Hankey's inquiry on the subject, in the House of Commons, by the Home Secretary. The result of the inquiry before a Committee of the House of Commons, last session, was the recommendation of a *Fire Police* for the metropolis. In my "Report on London Fires in 1844,"* remarking on the unsuccessful attempt of Lord Lincoln to introduce a Fire Bill for the metropolis, I observed that, "To an efficient and well-organized *Fire Police* we *must* come at last; and it seems strange, that, while so many of the provincial towns have for years past been thus provided, the metropolis should so long be left to shift for itself. The conduct of the police at fires has generally been of a very satisfactory description. In some instances great want of judgment has characterized their exertions; but in the majority of cases, their efforts have been most praiseworthy, and quite enough has been done to show that, if properly appointed and instructed, the police are calculated to render the most effectual assistance upon all occasions of fire, thereby refuting—were it not already strikingly refuted by the *Liverpool* practice—the fallacy of a statement recently put forth, that 'to add to the numerous and varied duties of the police that of *firemen*, would only be to confuse them.'" This opinion expressed by me nearly twenty years ago is now becoming general.

Prior to the appointment of the Parliamentary Committee, the Insurance Companies had officially notified to Government their desire to transfer to some properly constituted body (*approved by them*) the fire-service of the metropolis. When before the committee, however, they expressed themselves not unwilling to continue their fire-engine establishment on an extended scale, if Parliament would grant a subsidy for that purpose. Many persons doubted the sincerity of their avowed intention to give up their present establishment; and it is pretty certain they will not do so, unless they are permitted to have a very large share in the control and management of any new organization.

They have been increasing the number of their men and engines, and have entered into fresh contracts with their engine-makers for one, two, or three years, showing a strong belief on the part of the Insurance Companies that some time may yet elapse before any satisfactory arrangement shall have been completed. And it has leaked out that the proposal to relinquish their fire-engine establishment was a proceeding, on the part of members of the younger offices, that was not approved of by the older ones, who are desirous of keeping the matter in their own hands. The original movers in the affair, now finding that they will not be permitted to control any new organization, are doing their best to lay the spirit they have raised, but they have gone too far to retract, and they may, perhaps, be compelled to accept the Government measure. The Insurance Companies now say that their fire-engine establishment is sufficient for their purpose; and if the suburban districts require better protection, they must provide it themselves.

The public, however, are not likely to put up with such a state of things, after the late agitation and inquiry, but will look for a systematic and well-organized protection, independent of insurance interests. The employment of steam fire-engines for land service has not hitherto proved economical; this has arisen partly from the peculiar construction of the machines, which are evidently of a kind not adapted to the work, but more particularly from the reckless running to which they have been subjected. In the last annual report of the Superintendent of Brigade, he says, "I am now enabled to have at least one land steam fire-engine, with steam up, at almost every fire." It is very well known that the steam fire-engine is not required at "every fire," nor yet at one fire in fifty. It was recently stated in a local paper, that last year "the steam fire-engine had attended forty-five fires, at which the damage was under £10; thirty-eight fires at which the damage was merely nominal, or under twenty shillings; at eighteen chimney fires; and at seventeen false alarms."

---

* Mechanics' Magazine, Vol. 42.

The consequence of this reckless running has been excessive wear and tear, necessitating continual visits to the repairing shop. The first land steam fire-engine of the fire brigade was used up in ten months; its successor, after twenty months' running, was found to require very extensive and costly repairs. A striking contrast to all this is furnished by Mr. Braithwaite's steam fire-engine the "Comet," built thirty years ago, which, without requiring any important repairs, is still in good working order at Berlin. Notwithstanding these discouraging circumstances, quite enough has been done to show that, if properly constructed and fairly used, steam fire-engines may be employed for extinguishing serious fires in the metropolis with advantage and with economy.

But prevention is better than cure; and the first object should be to establish in the metropolis such a fire service as will ensure assistance being given in all localities within ten or fifteen minutes after the first discovery of a fire, to be promptly followed by means equal to the requirements of the occasion. Under such a system serious fires would be greatly diminished both in number and extent.

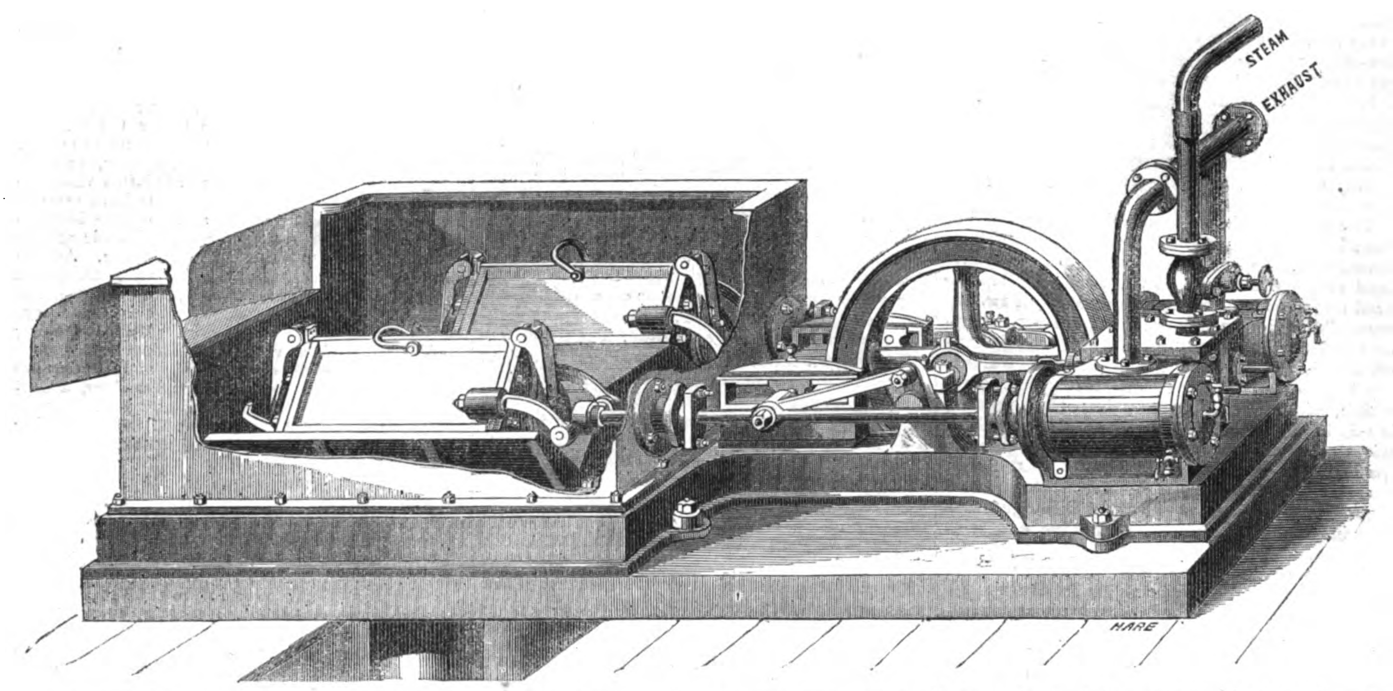
SCOTTISH SOCIETY OF ARTS.

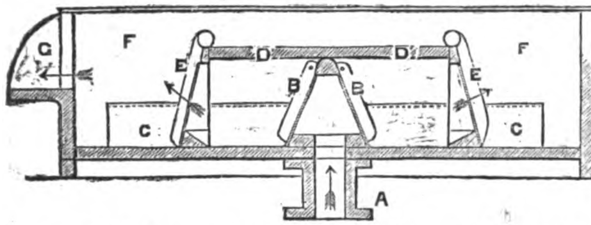
At the ninth meeting of the session of the Royal Scottish Society of Arts, in Edinburgh, on Monday, Mr. William Paterson, C.E., gave a description of an improved signal and method of working single lines of railway without accident. The method suggested by Mr. Paterson was, carrying out the suggestion of Captain Tyler in his report on the Winchburgh railway accident, that main signals, as well as distant signals, ought to be placed at both ends of single lines; that distant signals, with the necessary gearing, be placed from 500 to 600 yards distant from each connection; that main signals be placed at the point where the two lines begin to converge to the point of junction, whether at crossing places or single lines, or where the double line is closed in one line. These last-mentioned signals it is proposed to improve by making them locked signals. The pointsman at either end would have full control of the respective distant signals, but not so of the main signals. In working, should an engine or train approach one end of the single line, and the pointsman, finding that it could not be let on (he not being in possession of the handle for opening the main signal) then in that case he would turn the distant signal to caution, and thereby permit the engine or train to draw in between the distant and main signals, the former being turned to danger so soon as the engine had past within it—in that way protecting the standing engine or train—and then so soon as the pointsman received the handle of the main signal (which could be carried along the single line either by the engine-driver or by the guard of a train, or by a pilot-engine) he would open it and permit the train or engine to proceed. The paper was remitted to the committee.—Mr. Joseph Polson, engineman, gave a description of a machine for blacking and brushing boots and shoes. The machine, he said, is very simple. The motive power is supplied in the same manner as in the ordinary turning-lathe. Brackets fixed to the frame support a double crank-shaft, from which the different brushes obtain their motion. At the operator's left hand is the dusting brush, a few moments' application to which is the first stage of the process. At the right hand is the blacking brush, which is fed from a small box, and by means of a connection rod, worked from the front of the machine, the supply is presented or withdrawn. The boot or shoe, so prepared, is then placed under the polishing brushes, steadied upon a small self-adjusting platform. The brushes, which are hollowed to suit the rounded shape of the boot or shoe, move horizontally with great rapidity, closely imitating the action of the arm. The brushes give about 300 strokes per minute, being about five or six times the number produced by a strong hand and arm. They are, moreover, given with perfect equality and steadiness, and with a capability of sustaining the work for any length of time. The brushes, which are worked from the double crank-shaft by means of connecting rods, move in the grooves of a framework supported by brackets. The inventor then exhibited the machine in operation. The paper was remitted to a committee for consideration.—Mr. Edward Sang communicated a description of a new horizontal windmill, invented by Mr. James Laird, caum maker, Forfar. Mr. Sang also gave a description of two new gravity escapements, invented by Mr. Henry Kerr, clock and watchmaker, Dundee. Both papers were remitted to committees.—Mr. Alexander MacLattie, F.C.S., lecturer on chemistry, Glasgow, gave a description of a new apparatus for aerating water distilled from sea water, invented and patented by Messrs. Chaplin and Russel. The thanks of the meeting were awarded to Mr. MacLattie.

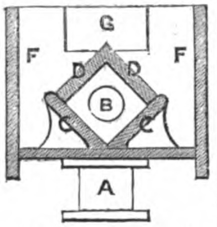
NEW THEORY OF STEAM GENERATION.

On Monday a Paper was read at the Liverpool Literary and Philosophical Society, accompanied by numerous experimental illustrations, "On a New Theory of the Generation of Steam, with an Explanation and Imitation of the Phenomena exhibited by the Geysers of Iceland," by E. J. Reed, Esq. The author commenced by remarking, that as a comparative stranger to the society he should not have ventured to put forward in their presence a new theory of steam generation had the theory been his own; but he felt sure that they would be glad to receive some account of what was, in fact, the result of experimental investigations that had been carried on for a series of years by a very distinguished townsman of theirs, Mr. Charles Wye Williams, whose labours had tended largely not only to distinguish Liverpool in the world of science, but also to benefit it greatly in a commercial sense by the establishment, as early as 1823, of steam trading vessels running between Liverpool and Dublin. The author next proceeded to point out the various and contradictory uses of the words "steam," "vapour," "vaporization," "evaporation," and "ebullition," which are to be found even in standard works of science, quoting from Dr. Thomson, Dr. Whewell, the writers of the *Encyclopædia Britannico*, and other authors, and stated that as a first step towards giving soundness, consistency, and utility to our knowledge of this subject, Mr. Williams had swept away all that jumble of competing and conflicting phrases, and had given to each of these words its distinct and legitimate signification. He showed that, from Dalton onwards, writers of the greatest eminence had admitted the absolute identity of vapour and steam, and that the only true signification of the word "vaporization" (as applied to water) is the conversion of water into vapour, that of "evaporation" being the escape of vapour from the water, and "ebullition" merely that particular mode of evaporation which arises from the aggregation of vapour into bubbles before and during its escape. The fiercest jet of steam is, in fact, nothing more or less than a compact stream of the self-same vapour that rises daily like incense from flower and field and sea, and floats in such beauty and splendour above us that an inspired writer was constrained to ask, "Dost thou know the balancing of the clouds, the wondrous works of him who is perfect in knowledge?" Strange to say, however, most of our philosophers, when they had come to study steam generation, had forgotten the familiar processes of vaporization and evaporation, and propounded the doctrine, that the effect of applying heat to water was no longer to vaporize the water, but to heat and expand it, and cause it to circulate until it all became of the elevated temperature of 212 deg. Then, and then only, did the formation of steam commence. The author then went on to show, by numerous experimental illustrations, that the first effect of applying artificial heat to water is, not to heat the water, as such, but to convert a certain portion of it into vapour, just as on a larger scale the natural heat of the sun converts the water of the earth into vapour, and brings about that magnificent meteorological paradox which the comprehensive eye of King Solomon discerned when he exclaimed, "All the rivers run into the sea, yet the sea is not full; into the place from whence the rivers came, thither they return again." When the subject first came under the author's notice, Mr. Williams drew his attention to the fact, that the rise of the generated vapour, and its diffusion through the liquid, were plainly visible to the eye—a discovery which seemed to have escaped all previous experimenters, and to have been reserved as a great reward for the scientific ardour and research of his friend, Mr. Williams. At this point of the paper, Dr. Edwards, the able analytical chemist of Liverpool, exhibited a most beautiful experiment illustrative of this discovery, by means of an electric light. On heat being applied to a glass vessel containing cold water, instead of the series of ascending and descending currents described by all previous writers, a continuous movement *upwards* of cloud-like vapour was made visible to the audience. After explaining this discovery at length, and demonstrating that the movements made visible were those of vapour, and not of heated currents of water, the author drew several important inferences from the phenomenon, such as that it is untrue to say, as many authors do, that vapour is formed at the *surface* of water only; that, water, even when of a low temperature, does not *condense* vapour, *i.e*, reconvert it into water; that water is capable of containing, and, when what is called warm or hot, does contain, uncondensed vapour or steam. These several doctrines were further illustrated by experiments (admirably carried out by Dr. Edwards), and their discovery, the author believed, rendered a revision of the common theory urgently necessary. By elaborate reference to the writings of Dalton, Faraday, and others, he further showed, that, apart altogether from the special experiments then considered, there were good philosophical grounds for urging such a revision. In referring to Dalton's doctrine of gaseous diffusion, and its bearing upon the new theory, the author mentioned incidentally that there was a peculiar fitness in the circumstance of the present discovery proceeding from Mr. Williams, seeing that in early life, and before Dalton announced his discoveries, his venerable friend was a pupil of Higgins's, whom Davy acknowledged to be the first discoverer of the atomic theory in its modern form. From the lips of that philosopher, he (Mr. Williams) had listened to the earliest enunciation of that theory, and later in life not only became an earnest student of Dalton's writings, but delivered at Manchester a lecture treating largely of gaseous diffusion, at which Dalton himself presided, and which received the full approbation of that illustrious man. The author finally referred to a class of phenomena to which little attention had been given, concerning which Mr. Williams had made many remarkable discoveries, and which was, in the author's opinion, inexplicable under any other theory than that which he had then explained, that class of phenomena being principally the ebullition excited by the introduction of foreign substances into masses of water to which considerable heat has been applied. The treatment of this part of the subject involved a discussion of "the boiling point" (and in reference to it Dr. Edwards again exhibited a brilliant series of experiments). The author concluded by saying he felt confident, that even while laying aside all that personal regard which the long and honourable residence of Mr. Williams among them must have excited, the audience would agree with him in believing, that as students and lovers of science, they must heartily admire both the zeal and the genius which he had brought to bear upon that profound and intricate subject. It was a subject in connection with which great successes had been achieved and great reputations made; but when he compared the confused and conflicting doctrines enunciated in our existing works with the clear and harmonious principles now presented to us in Mr. Williams's work, "On Heat in its Relation to Water and Steam," (lately published by Longman and Co., of London), he could not help thinking that his name deserved, and would ere long attain, a place as high and as illustrious as those of even the most distinguished discoverers in that beautiful and profound branch of science. At the close of the paper Mr. Reed explained the perfect manner in which the action of the Geysers of Iceland was accounted for by Mr. Williams's new theory, illustrating the subject by the exhibition of a powerful artificial

NORTON'S V-SHAPED PUMPS.







Geyser, which had been prepared by Mr. Williams himself, and by which the violent and intermittent, but very copious discharges of steam which occur in the boiling springs of Iceland, were imitated in a most remarkable and interesting manner.

At the conclusion of the Paper a discussion ensued, in which several gentlemen took part, and a vote of thanks having been carried by acclamation to the lecturer, and also to Mr. C. Wye Williams, who was present, the meeting was adjourned at a late hour.

NORTON'S PATENT V-SHAPED PUMPS.

The woodcuts given above represent a perspective view of a steam-pump of a simple construction, as regards both the mechanical details and facility of access to the working parts. Besides these advantages, the unavoidable wear and tear of the moving parts incidental to all metal surfaces tend rather to keep the pump in repair, instead of deteriorating it. As no packing is required, or the attention of a skilled labourer necessary to keep the machine in working order, its advantages recommend its adoption under circumstances where pumps of a more complicated description would be scarcely applicable.

The amount of power required to raise a certain quantity of water to a given height is theoretically fixed; the difficulty in engineering being to make working machinery approximate as nearly as possible to scientifically ascertained data, and when that approximation has once been attained, to have a machine applicable to every-day use that shall maintain its qualities without the constant supervision and "doctoring" that the "wear and tear" natural to all materials usually involve—in fact, to construct something that shall always wear itself true, instead of wearing "out of truth." Results when once obtained by scientific experiments may be reproduced *ad infinitum*, if the right means be taken; but the great obstacle o continuous repetition is the want of durability of the materials used; and their lasting powers, in good working order, are the limits of the truly effective action of any machine. Instead of using a cylinder and plunger, or piston, which requires packing, and is constantly *wearing loose* and becoming leaky by continuous action, the inventor substitutes a V *bed and a moving* V working therein, which does *not* require packing, and is constantly *wearing true*, even supposing the original to be imperfect, until the material of which it is made is actually worn away.

The accompanying sectional diagrams will explain how this is attempted. A is the suction pipe of the pump leading to the well or other place from which the water is required to be raised. B B, are two valves opening right and left, so as to allow the water to pass out in the direction indicated by the arrows, and forming part of a centre piece in the V-shaped bed C. D is a sliding V, having two top sides and two ends, also provided with valves E E; the two top sides combined with the V bed, forming a diagonal square box opening right and left into a tank F, having an overflow spout at G, from which the water is discharged. The moving V and the V bed when together, form a rectangular chamber closed in by end pieces forming part of the moving V. All the valves are of the simplest form of hanging flap valves, and are at any time got at in case it is required, by merely lifting the box D, which can be done in the heaviest pumps by a labourer without having to unscrew a single bolt or nut to interfere with any working parts, and in replacing the box, it would be impossible to do so in any but the right position, even if it were desired.

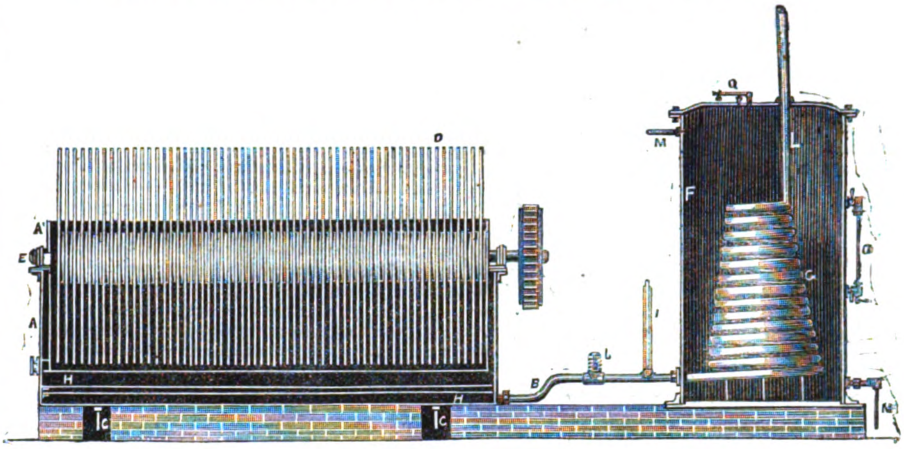
The action of the pump is as follows:—If the box D is pushed towards the right hand, it forms a vacuum on the right-hand side between the anti-piece and the end of the moving V, and any water on the left-hand side is expelled through the valve into the tank F. By moving it towards the left, a vacuum is formed to the left, and the water on the right is expelled into the tank; in both cases the surplus water in the tank escaping by the overflow spout G, so that by imparting a reciprocating action to the box D a constant flow of water *upwards* is maintained in the pipe A, and a constant overflow from the discharge spout G. In the two pumps shown in the engraving the reciprocating action is given to the pumps by a pair of steam cylinders, having pistons, the rods of which are connected with the moving V's, the whole being self-contained on the same base-plate. The results obtained by these pumps are said to be very satisfactory. For force pumps it is merely necessary to cover in the top of the tank F, and convert the spout G into a pipe leading to any place required.

NEWNAM'S APPARATUS FOR CRYSTALLIZING AND EVAPORATING.

Mr. J. Newnam, of Crayford, Kent, has obtained a patent for an invention for "improvements in apparatus for crystallizing and for evaporating." This invention consists in the combined employment of a closed pan with steam inlet and steam and condensed water outlet, of revolving discs which revolve partly in the atmosphere and partly in the matter being operated on, and of a vessel containing a worm or pipes communicating with the pan, and through which steam is made to pass. A gauge is fitted on the pipe which communicates between the vessel and the pan, and also a safety valve.

The accompanying engraving is a longitudinal section of an apparatus for crystallizing and evaporating, constructed according to this invention. A is the closed pan, B is the steam inlet, and C C are steam and condensed water outlets. D D are discs mounted on a shaft E, revolving partly in the atmosphere and partly in the matter being operated on, which is contained in the vessel A^1. F is a closed vessel, containing a worm or pipes G, through which steam is made to pass to the pan A. H H are perforated plates in the pan A for distributing the steam uniformly over the whole interior surface of the pan. I is a gauge, and a safety valve is on the pipe which communicates between the pan A and the vessel F. A safety valve is likewise fitted on the side of the pan A. The matter to be operated on is supplied to the vessel A^1, the bottom of which forms the top of the pan A. Steam is admitted into the worm G from the pipe, and is reduced to the pressure required by cold water supplied to the vessel F when required by the pipe M. N is an outlet pipe fitted with a cock for drawing off water from the vessel when the steam does not require attemperating. The height of the water in the vessel F is indicated by the gauge O, and the pressure of the steam is shown by the gauge I. The steam from the worm G passes through the pipe B into the pan A, all increased pressure being prevented by the safety valve J. On entering the pan the steam is uniformly distributed therein by means of the perforated plates H, the pan becomes heated, and the heat is transmitted to the matter under operation, which is kept agitated by the revolving discs D D; the liquid portions are gradually evaporated, and the matter, where capable of crystallization, crystallized. The steam which becomes condensed in the pan passes off by the outlets G G. The vessel F is furnished with a safety valve Q. Instead of causing the steam to pass through the worm G, and the cold water through the vessel F, as hereinbefore described, the steam may be made to pass through the vessel and the cold water through the worm.

NEWNAM'S APPARATUS FOR CRYSTALLIZING AND EVAPORATING.

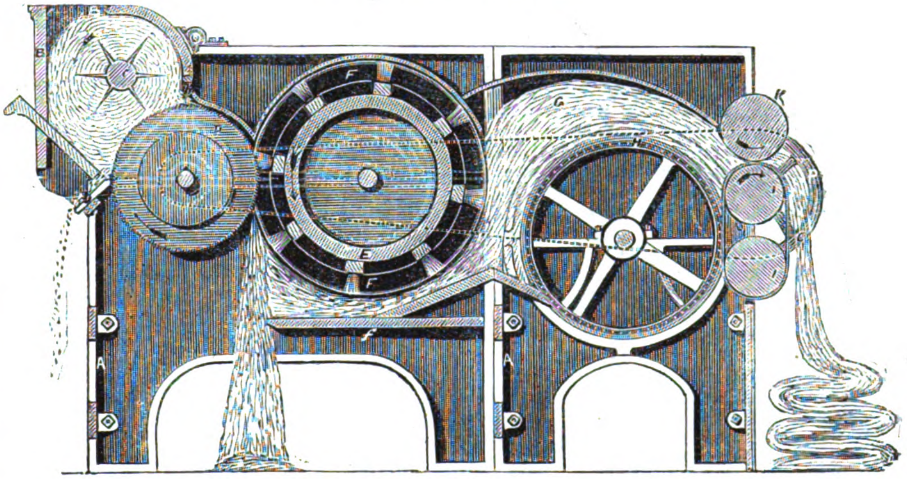


EMERY'S MACHINERY FOR GINNING COTTON.

Mr. H. L. Emery, of 72, Sloane-street, Chelsea, has just patented an improvement in machinery for ginning cotton. The object of this invention is so to improve the saw gin as to effect the ginning of long and short staple cotton in a more efficient and economical manner than heretofore, and effectually to remove the sand and dust from the cotton. At the front part of the machine the hopper is mounted on a hinged joint, as usual, to allow of its position being adjusted by the attendant for the purpose of regulating the action of the saws upon the staple. Within the hopper is mounted a spiked roller, its use being to lap around it the cotton as it is fed into the hopper, and thereby to present the staple in the form of a roll to the action of the saws. This roll may receive motion through gearing from the saw shaft, but it is preferred to mount it loosely in bearings formed by elongated holes in the ends of the hopper. The inner side or breast of the hopper is formed as usual of upright bars which constitute a grid. Between these bars the saws (set at equal distances apart on a common shaft) project to take hold of the roll of cotton, and detach the fibres from the cotton seed. As the saws revolve they give rotary motion to the roll of cotton in the act of drawing out the fibres therefrom, and as the cotton is withdrawn from the hopper by the saw teeth, the cotton seeds are discharged through the bottom of the hopper. The saw teeth, as fast as they become charged with cotton fibres, are stripped by a rapidly revolving brush cylinder, which is mounted in a chamber in the rear of the line of saws. This brush cylinder, by its rapid rotation, creates a blast of air that passes up between the cylinder and an inclined conducting board, on to which the cotton is delivered; from this board the ginned cotton passes (assisted by the blast) into a taper-mouthed air-trunk connected with the air-chamber. In this air-trunk a drum of wire gauze is mounted horizontally. The cotton, as it enters the air-trunk, is taken up by the drum, which receives a slow axial motion. The drum, in its rotation, carries the cotton upwards in the form of a thin sheet, and presents it to the action of the blast, so that the sand and dust contained in the cotton is discharged therefrom, and falls through the wire gauze drum to the ground. The cotton, as it passes round, is stripped from the drum by a stripping roller, and passed between a pair of smooth rollers, which deliver it in a condensed form, and in a continuous length out of the machine.

A is the main framing of the machine, at the front of which is a hopper B; this hopper is mounted on a hinged joint *b*, capable of receiving an endway movement to allow of the position of the hopper being adjusted by the attendant for the purpose of regulating the action of the saws upon the staple. Within the hopper is mounted loosely a spiked roller C, its use being to lap around it the cotton as it is fed into the hopper, and thereby to present the staple in the form of a roll to the action of the saws. This roll may, if desired, receive motion through gearing from the saw shaft, but it is preferred to mount it loosely in the hopper, and make it dependent for its rotation on the contact of the saws with the roll of staple.

EMERY'S COTTON GIN.



The bearings of the spiked roller consists of elongated holes in the ends of the hopper, the lower edge of the holes being of a segmental form struck from the axis of the saws, and the upper part being sufficiently concave to allow the roll of cotton to rise, and thereby escape a too severe action of the saws. The inner side or breast of the hopper is formed, as usual, of a series of upright curved bars *b*, which are set parallel to each other, and constitute a grid. Between these bars the saws D (set at equal distances apart on a square shaft) project to take hold of the roll of cotton, and detach the fibres from the cotton seeds. As the saws revolve they give rotary motion to the roll of cotton in the act of drawing out the fibres therefrom, and as the cotton seeds are stripped of the cotton by its withdrawal from the hopper by the saw teeth, the seeds fall out from the roll, and are discharged through the bottom of the hopper.

As fast as the teeth of the saw become charged with cotton fibres they are stripped by a rapidly-revolving brush cylinder E, which is mounted in a chamber F, in the rear of the line of saws. This brush cylinder, which is intended also to act as a blower, is closed at its ends by annular trough-shaped end plates, and segmental openings are made in the sides of the chamber F opposite the upper half of the annular trough to allow of an indraught of air to the chamber. The rapid rotation of the brush cylinder also draws air between the cylinder and a conducting board *f*, forming the bottom of the chamber, against which the cotton is thrown by centrifugal force. From this board the ginned cotton is carried by the action of the blast into an air-trunk G connected with the air-chamber F. In this air-trunk a drum of wire gauze H is mounted horizontally for the purpose of receiving the cotton on its surface in the form of a batt. To this drum a slow axial motion is imparted for the purpose of conveying the cotton as it is deposited upon the upper part of its periphery to an endless belt on a pair of stripping rollers I, I, and presenting a fresh surface to be coated by the cotton discharged into the air-trunk. The drum in its rotation carries forward the cotton in the form of a thin sheet, and presents it to the action of the blast, the only vent for which is through the wire gauze drum; the sand and dust contained in the cotton is therefore carried away by the blast, and falling through the drum H, is deposited on the ground. The cotton passes under a smooth pressing roller K mounted above the stripping rollers, by which means it is delivered in a condensed form, and in a continuous length out of the machine, as shown.

The use of the spiked roller is to support the feed of cotton in such a manner that it will ensure an equable rolling motion of the mass of cotton in the hopper, and thus prevent the unequal drag of the saw teeth upon different parts of the feed, which inequality of drag occasions the formation of twists and knots, and the consequent cutting and destruction of the staple.

A further important advantage incidental to the use of the spiked roller which forms a supporting core to the roll of feed cotton, is that it enables the machine to be driven either at high, low, or variable speeds without injury to the staple, and that with a considerably reduced expenditure of motive power as compared with saw gins fed in the ordinary manner. The ends of the brush cylinder are closed, and air enters the machine past the closed ends of the cylinder. By this arrangement, the liability of the cotton to accumulate about the axle of the cylinder is removed, and the common danger of fire resulting from the friction on such accumulation of cotton is also removed.

In order to adapt the machine when set for short staple to act on long staple cotton, every alternate saw is removed and replaced by plain discs of the same diameter. By thus increasing the distance between the saws, no two sets of teeth can by any chance actu pon the same individual fibres, and therefore the cutting of the long fibres by the saws will be effectually prevented.

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY.

At the ordinary meeting, on April 7th—E. W. Binney, F.R.S., F.G.S., president, in the chair—a Paper was read, entitled "Note as to two Events in the History of Steam Navigation," by W. J. Macquorn Rankine, C.E., LL.D., F.R.S., Hon. Member of the Society.

1. An interesting Paper was lately read to this society by Mr. Dyer, containing a history of a series of important events in the progress of steam navigation.

2. It is to be regretted, however, that the author has noted, either very slightly or not at all, what appears to have been an event of paramount importance in the first adaptation of the double-acting cranked steam engine to drive a paddle-wheel. Before that adaptation was made, the success of all attempts at steam navigation, such as those of Jouffray, Rumsey, Titch, Miller, and Taylor, &c., had been only temporary, because of the rudeness of the machinery for communicating motion from the piston to the shaft.

3. The first adaptation was unquestionably accomplished by William Symington in 1801, as is proved by authentic documents which have been published by Mr. Woodcroft in his "Origin and Progress of Steam Navigation." Symington, instructed by the failure of the ratchet-work engine which he had made for Miller's boat, fitted up the "Charlotte Dundas" in 1801, with a double-acting horizontal cranked engine, and this made her what Mr. Woodcroft has justly called "the first practical steamboat." Her speed, when running alone, and not towing other boats, was six miles an hour.

4. The use of this vessel was abandoned, not from any fault in her construction or working, but because the directors of the Forth and Clyde Canal feared that she would damage its banks. Yet the man in all Britain who possessed, at that time, the greatest practical experience of the working of canals—the Duke of Bridgwater—was not deterred by any such apprehension from ordering, in 1802, eight similar vessels, from Symington, to be used on his canal.

5. The death of the Duke of Bridgwater, early in the following year, prevented the execution of that order. But Symington had evidently done all that lay in his power, and all that was necessary, to convert the steamboat from an awkward piece of experimental apparatus to a practically useful machine; and the honour paid to his memory ought not to be lessened because the career of his invention was cut short by a misfortune.

6. There is nothing in this to detract from the honour which is justly paid to Fulton, as having been the first to practise steam navigation on a great scale, as a commercially profitable art.

7. Another event passed over in the Paper to which I have referred, is the first introduction of commercial steam navigation into Europe, which was effected on the river Clyde, in 1812, by Henry Bell, as is proved by documents cited in Mr. Woodcroft's work, already referred to.

Dr. R. Angus Smith said that he had been using an amalgam of sodium for the production of hydrogen. When doing this it was found that the amalgam had become one mass of crystals. These crystals are fine needles or prisms of considerable length; some may be traced in the tangled mass for about half an inch; they present hollow ends, although it was not possible to trace this hollowness through the whole length of the crystals. They are hexagons, and contain 9·47 per cent. of sodium; an excess of mercury remains; 10·3 per cent. would be equal to 2 at. of mercury and 1 of sodium. He had not seen any notice of an amalgam of a similar composition. It can be examined only through glass, as it rapidly absorbs oxygen from the moisture of the air, and cannot be retained in the air many seconds without changes being perceived. If this change be examined under a microscope, bubbles of hydrogen are seen to rise from every corner, extremely minute certainly, so that many millions would be required to cover a square inch, but affording one of the most convincing and direct proofs of the existence of moisture. This property may in many cases be found to be of value. The inclination to combine with oxygen when dry seems comparatively slight.

MIDDLE LEVEL DRAINAGE.

At the meeting of the Institute of Civil Engineers, on Tuesday last, the Paper read was "Account of the Coffer Dam, the Syphons, and other works, constructed in consequence of the failure of the St. Germain's Sluice of the Middle Level Drainage," by Mr. Hawkshaw (President Inst.C.E.).

The St. Germain's Sluice was situated at the confluence of the Middle Level main outfall drain with the River Ouse, near the upper end of the Eau Brink Cut. This drain was made in 1847, from the designs, and under the direction of Messrs. Walker, Burges, and Cooper. It was deepened by them in 1857, and then had, at the lower end, a bottom width of 48 ft., the side slopes being 2 to 1. The level of the bottom was 7 ft. under low-water spring-tides in the river, and the rise of the tide at that point was about 19 ft. at spring-tides, the sill of the sluice being 6 ft. below low-water spring-tides. The bed of the drain was of soft blue clay, and the sides consisted of variable thicknesses of soft blue clay, peat, yellow clay, and surface soil.

On the 4th May, 1862, the St. Germain's Sluice gave way, thereby admitting the tidal waters, which ebbed and flowed throughout a distance of upwards of 20 miles. A few days afterwards the western bank of the Middle Level drain burst, about 4 miles from the sluice, by which 6,000 acres of land were inundated. Immediately after the failure of the sluice, the author received instructions to execute whatever works might be necessary to shut out the tidal waters, regardless of expense. The services of Mr. J. T. Leather were secured as contractor, who was ably aided by his assistant, Mr. E. P. Smith. Mr. Alexander G. Linn was appointed resident engineer. Subsequently, after the coffer dam was closed, finding it impossible to devote so much time to the works as he had previously done, at the author's request, the Middle Level Commissioners associated with him Mr. T. E. Harrison, who had since continued to act.

Before the author assumed the direction of the works, and directly after the failure of the sluice, an earth and cradle dam was attempted to be thrown across the drain, at about 500 yards from the fallen sluice. This was relinquished shortly after the permanent coffer dam, of pile-work, was commenced; which the author considered was the only plan likely to be effectual, and the site finally fixed upon for which was about 880 yards from the sluice. The coffer dam might be thus described:—Temporary piles were first screwed into the ground, upon which a staging was erected for the pile-driving engines. Two rows of sheet-piling, 25 ft. apart, were then driven transversely down the slopes of the drain on each side, from the centres of the banks to within 20 ft. of the bottom, leaving a central space of 88 ft. of coffer dam to be afterwards completed. In this portion of the dam the piles were placed in pairs on each side, 7 ft. 6 in. apart from centre to centre, and with a space of 7 in. between each pair. The grooves thus left were for the reception of sliding panels, to be used to fill up the intervals between the several twin piles. Waling pieces of whole timbers were fixed to the inside and the outside, both at the top and as near the level of low-water as possible. As the piles were driven, struts and ties were inserted, and strongly-framed raking struts were secured against the dam and against abutments of piles, backed with concrete, on the land. The panels were composed of timbers 7 in. thick, and of variable lengths, firmly bolted together, and further connected and weighted on one side by flat wrought-iron plates. In order to put these panels in place, a frame was erected, from which they were suspended, and from which they could be lowered, and raised, if necessary, by pulleys.

The rush of water through the dam was materially increased, when the piles for the panels and the walings were in place; so that, at times, the difference of level between the water on the two sides of the dam was considerable. Aprons, extending the whole width of the drain, and for some distance up the slopes, were formed on both sides of the dam, of sacks of clay, and of gravel, puddle, and stone. Only sufficient stone was deposited in the centre of the dam to stiffen the clay; but large quantities of puddle were repeatedly thrown in at slack water, most of which was washed away by the rush of water, which acquired a velocity of 8 miles an hour.

The first, or lower tier of panels, was 7 ft. deep, and pointed at the lower end, so as to be driven into the mud. Inasmuch as they could not be driven to the same depth, the second set was so arranged as to raise the panelling to the uniform height of low-water spring-tides. During these operations, sacks of clay and gravel were deposited on the inside and the outside of the dam; but, although the aprons were extended, only a few sacks of gravel remained in the inside. It now became clear that the water could only be excluded by shutting the dam at one operation. To accomplish this, the necessary panelling, which had to be 12 ft. deep, was suspended from the scaffolding, so as to be dropped into place at slack-water neap-tides, when the differential head for the dam to sustain was the least. On the first attempt to close the dam, three of the twin piles on the lower side gave way, releasing some of the bottom panels, after the tide had receded 3 in., and when there was a head of 8 ft. The other panels were readily lifted and removed; and sheet-piling was then driven up to the level of the lower waling pieces, thereby filling in the spaces between the broken piles. The second attempt, which proved completely successful, was postponed until the succeeding neap-tides; when the panels were dropped into their places in twenty minutes, at low-water of ebb tide, that time being more convenient, the difference of the head at high and low water not being considered of sufficient importance to counterbalance other advantages. After the panels were lowered, the inside of the dam was immediately filled with clay: sacks of gravel and clunch being deposited in the centre. So complete were the arrangements, that the raising of the dam was kept in advance of the rise of the tide, and before high-water the operation was completed, the dam not exhibiting the slightest indication of failure, or of weakness. The coffer dam was commenced on the 16th of May, and the tidal waters were shut out on the 19th of June, 1862.

During this time, the means to be adopted for the future drainage of the Middle Level received serious attention. After careful consideration, the author determined that, in addition to such drainage as could be obtained through Salter's Lode Sluice, the old outlet into the Ouse, syphon pipes should be laid over the coffer dam. This plan of discharging water was not to him novel, having pursued it in 1839, when engaged on the Manchester, Bury, and Bolton Canal. The syphons were sixteen in number, and were laid transversely across the dam, at an inclination of 2 to 1 at the sides, and horizontally over the top. Each end was terminated by a horizontal length, containing the upper and lower valves, laid 18 in. under low water of spring tides, the top of the syphons being 20 ft. above the same level. The total length of each syphon was 150 ft. The syphons were of cast-iron, 3 ft. 6 in. internal diameter, and the thickness of the metal was (excepting at the socket ends, where it was thicker) 1½ in. They rested on the top of the dam, and on inclined framework, supported on piles at the sides. Underneath the extreme ends of the syphons, sheet-piling was driven across the drain. Above the sheet-piling, the spaces between the inclined framework, to the under side of the syphons, were filled in with clunch, clay, and gravel, so as to form a solid and impervious embankment. The bottom of the dam, at the inlet and outlet of the syphons, was protected by substantial wooden aprons, extending across the drain; and a row of piles was driven on each side, inclining towards each other, and contracting the channel to a width of 60 ft., so as to keep the "wash" off the slopes of the drain. The upper, or inlet, valve consisted simply of a loose hanging flap of teak wood, working inwards as soon as the outward was the preponderating pressure. The lower, or outlet, valve was of cast iron, turning on a hinge at the top, and fitted with a balance weight, which was capable of resisting an interior pressure, but could be readily released when the valve was converted into a flap opening outwards. The reason for adopting two valves was for the purpose of enabling the syphons to be put into operation, either by exhausting the air, or by filling them with water; but at present only the former method had been tried.

The syphons were put into action by exhausting the air from the inside, by an air-pump having three cylinders, each 15 inches diameter with a length of stroke of 18 inches, worked by a 10-horse power, high pressure, steam-engine. Each syphon could be shut off, or be brought into operation at pleasure, by means of slidecocks, fixed on vertical pipes, communicating with a transverse horizontal pipe in connection with the air-pump. An overflow pipe showed when the syphons were full of water; and glass gauges were also attached to some of the syphons for the same purpose. The pipes were cast by Messrs. Cochrane and Co., and the steam-engine and air-pump were manufactured by Messrs. Easton, Amos, and Sons.

After the breach occurred, it became evident, that all attempts to stop it should be abandoned. The area flooded was surrounded by banks, which confined the mischief within certain limits. As soon as the coffer dam was completed, and the tidal waters were excluded, the breach was closed, by first tipping stone to form a footing for an embankment of clay to the level of the bottom of the drain, above which a small quantity of clunch was mixed with the clay, to stiffen and weight it. The total quantity of material used to restore the bank was about 25,000 cubic yards. The bottom of the drain, where the scour had taken place, was also repaired, and the banks generally were put in good order. After the breach was secured, the water on the inundated land was let off, through the Marshland Smeeth and Fen drain and the adjoining Marshland sewer.

In conclusion, the author remarked, that he believed the syphons would be found to answer all the purposes of a permanent sluice. They possessed, moreover, the advantage of not rendering the safety of a district dependent upon single pairs of gates; for it was clear, that any one or more of the syphons might be damaged or destroyed, without affecting the operation of the others, or endangering the district.

In an appendix tables were given, showing the quantities of the several materials used in the construction of the dam and syphons, as well as the results of the working of the syphons.

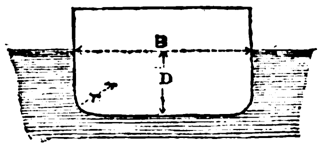
ON SECTIONS OF LEAST RESISTANCE FOR SHIPS OF LIMITED BREADTH AND LIMITED DRAFT OF WATER.*

As the friction of water along the submerged surface of ships forms an important part of the resistance to be overcome, it is desirable that this surface be the smallest possible consistent with other conditions.

The common problem of passing a curve of a given length through two points so as to enclose the greatest area between the curve and the straight line joining the points, may be applied to the construction of all vessels whose breadth and draft of water are not limited.

But there are many cases where both the breadth and draft of water are limited, it may be by the width of dock entrances and the depth of rivers. Then the problem becomes, to enclose within a rectangle of a given breadth and depth the greatest area with the least wetted boundary, that the enclosed area, divided by the wetted boundary, may be a maximum; for then, whatever form it may be considered necessary to give to the water lines, the vessel of this breadth and draft of water, with this midship section, these water lines, and with the narrow sections constructed on the same system, will have the greatest displacement or volume below water with the least surface for friction, and therefore the least resistance. In this sense I have called them sections of least resistance.

To construct these sections, the problem reduces itself to finding the radius of bilge, which, with the given breadth and draft of water, shall complete the section, whose area, divided by the wetted boundary, shall be a maximum.



Let B be the breadth of the vessel.
D the draft of water.
r the radius of bilge.

$$\frac{\text{Area of section}}{\text{Wetted boundary,}} = \frac{B\,D - 0{\cdot}429\,r^2}{B + 2\,D - 0{\cdot}858\,r} \text{ is to be a maximum.}$$

Therefore,

$$\frac{0{\cdot}858\,r\,d\,r \times \text{denominator} - 0{\cdot}858\,d\,r \times \text{numerator}}{(\text{Denominator})^2} = 0$$

$$\therefore r \times \text{denominator} = \text{numerator}$$

$$(B + 2\,D)\,r - 0{\cdot}858\,r^2 = B\,D - 0{\cdot}429\,r^2$$

$$0{\cdot}429\,r^2 - (B + 2\,D)\,r = -B\,D$$

$$r^2 - \frac{(B + 2\,D)\,r}{0{\cdot}429} = -\frac{B\,D}{0{\cdot}429}$$

A quadratic equation from which the radius r is found,

$$r = \frac{B + 2\,D - \sqrt{B^2 + 4\,D^2 + 2{\cdot}284\,B\,D}}{0{\cdot}858}$$

Examples.

When $D = 4\,B$ $r = 0{\cdot}114\,D$ when $D = \infty$ $r = \frac{B}{2}$
$D = 2\,B$ $r = 0{\cdot}23\,D$ $B = \infty$ $r = D$
$D = B$ $r = 0{\cdot}35\,D$
$D = \frac{1}{2}\,B$ $r = 0{\cdot}54\,D$
$D = \frac{1}{3}\,B$ $r = 0{\cdot}63\,D$
$D = \frac{1}{4}\,B$ $r = 0{\cdot}70\,D$

By describing sections in a rectangle whose breadth equals twice its depth, it will be found that

$$\frac{\text{Area of rectangle}}{\text{Wetted boundary}} = \frac{2\,D_2}{4\,D} = 0{\cdot}5\,D$$

$$\frac{\text{Area of semicircle}}{\text{Wetted boundary}} = \frac{\frac{1}{2}\,\pi\,D_2}{\pi\,D} = 0{\cdot}5\,D$$

$$\frac{\text{Area of best section}}{\text{Wetted boundary}} = \frac{2\,D^2 - 0{\cdot}43 \times (0{\cdot}54\,D)2}{4\,D - 0{\cdot}86 \times 0{\cdot}54\,D} = 0{\cdot}531\,D$$

showing that when the radius of bilge is 0·54 times the draft of water, there is a gain of about 6 per cent over the semicircular or rectangular section.

Professor Macquorn Rankine said that he had revised the mathematical investigation in Mr. Napier's Paper, and could corroborate its accuracy. Its practical utility arose from the fact that the whole, or nearly the whole, of the resistance to the motion of a well-shaped ship arose either directly or indirectly from friction. A theory based on that fact had been applied to practice in designing steam-ships and their engines by Mr. Napier and himself, in December, 1857, and subsequently, and in every instance with success. He had read a Paper giving a general account of the theory, and an explanation of the practical formulæ deduced from it, with tables of comparison between their results and those of experiment, to the British Association in 1861. That Paper was published entire in the *Civil Engineer and Architect's Journal* for October of that year, and, in part, in other engineering periodicals also.* The theory was connected with some researches on the motion of waves, which were read in abstract to the British Association, and in full to the Royal Society in 1862.

As might be expected in a theory whose practical application was only four years and a half old, various questions still remained to be settled by experiment. A serious obstacle in the way of obtaining exact experimental data as to such questions arose from want of precision in the indicator-diagrams of steam engines, especially in engines of rapid stroke, which was produced partly by the friction of the indicator, but chiefly by the oscillations of its spring. One of the best means of diminishing the extent of these oscillations, and the effect of friction at the same time, was to increase the stiffness of the spring and diminish the mass of the indicator-piston. He had seen at the International Exhibition an indicator (that of Mr. Richards) in which that principle had been adopted, and, so far as he could judge from having seen it in action two or three times, with very good results in point of precision.

A comparison of the diagrams given by a very accurate indicator applied to the engines of such vessels as the "Admiral," the "Athanasian," the "Lancefield," &c., would settle some very important points regarding the comparative advantages of straight and hollow water lines, &c. Unfortunately, when vessels were engaged in trade it was difficult to find opportunities for making scientific experiments upon them.

The special subject of Mr. Napier's Paper, however, was not one of those problematical points; for there could be no doubt that, to diminish a vessel's mean girth, as compared with her sectional area, was a certain means of diminishing resistance; that principle, indeed, had been admitted ever since friction had been recognized as one of the causes of resistance; and Mr. Napier's investigation showed how to carry that sort of diminution as far as possible under the circumstances stated by him—viz., a fixed extreme breadth and draft of water.

The importance of smallness of girth in diminishing resistance was strikingly shown in the case of the well-known match between the yachts "Titania" (now called the "Themis") and "America." The "Titania" was the smaller vessel of the two, and had the less capacity for carrying sail; and in order to make her speed equal to that of the "America," her friction ought to have been less in the same proportion with her capacity for carrying sail. But while the cross-sections of the "America" were nearly triangular, those of the "Titania" were formed by ogee curves of great concavity, producing a comparatively large girth relatively to her capacity; and although the "Titania" had a smaller midship section than the "America," the quantity called the "augmented surface," upon which the friction depends, was almost exactly equal in the two vessels, and hence the "Titania," having the less power of carrying sail, was beaten in the race.*

Professor W. Thomson said that he was glad to find that true principles as to the resistance experienced by solids moving through fluids were being applied in practice with such valuable results. The theory which had been hitherto commonly given in treatises on hydrodynamics, was founded on a calculation in which only the front part of the surface of the moving body was taken into account. It was no doubt convenient to neglect the action on the remainder of the surface; for to have included it in the account would have led to the awkward result *of no resistance at all!* Such a theory clearly is wanting in some essential. This we now know to be the reckoning of effects due to the viscosity of the fluid. A probable hypothesis as to the law of viscous force having been adopted, a perfect theory of the motion of a solid through a fluid, at a slow rate, *when no eddies are formed*, had been indicated and worked out in some important cases by Professor Stokes. It gives a resistance simply proportional to the velocity. But when the motion is so rapid as to give rise to eddies, which it always is in practical cases of water flowing through pipes and of ships, the circumstances become extremely complicated. Professor Thomson believed that the principles for obtaining practical solutions for the cases of ships were those which Mr. Napier had used in his investigation now before the Society. He concluded by saying that he had had much pleasure recently in testing, by personal experience of a voyage in the "Lancefield," some of the results of the application of these principles.

Mr. Napier said, that before commencing the construction of the "Admiral," to which Professor Rankine has referred, he applied to Professors Thomson and Rankine for advice as to the power necessary to propel vessels of any form, as his own experience led him to disbelieve the common theories based on the midship section or displacement. Professor Thomson stated then what he has now said regarding the friction of water, and Professor Rankine said, that if the resistance was the same as water in a pipe, the power required to propel his vessel at the given speed would be so many horse. The idea of water in a pipe having anything to do with the speed of a boat was strange and new to him; nevertheless, the power named was about two-thirds of what he had estimated to be necessary. A few days after making this approximation to the power, he had from Professor Rankine a formula, to which his notes supplied the data. This formula enabled him to make a vessel whose success was unprecedented.† The lines of the vessel were trochoids, with a cylindrical or prismatic middle, and as the breadth was unlimited and the draft of water limited, he made the radius of bilge equal to the draft of water, so as to have the surface a minimum. The "Athanasian" is also a trochoidal vessel, with a very short prismatic middle, and sections giving a minimum of surface. The "Lancefield" is similar to the "Athanasian," except the bow, which is a wedge, touching the trochoids at their points of contrary flexure. There are other peculiarities, however, in the "Lancefield" to which some of the economical results described by Professor Thomson may be due.

---

* Read before the Glasgow Philosophical Society, by James Robert Napier.

* The Mechanics' Magazine, the *Practical Mechanics' Journal*, and the *Engineer*.

* The "Titania" or "Themis" here referred to is the "Old Titania." The yacht now called the "Titania" is a vessel of a better model.—W. J. M. R.

Meetings for the Week.

Mon.—*Medical.*—At 8.30 p.m.
Geographical Soc.—I. "Visit to Ode, capital of the Tjebu Country, Western Africa," by Captain Bedingfield, R.N. II. "Explorations of the Elephant Mountains, in Western Africa," by Capt. R. Burton. III. "Travels in Equatorial Africa," by W. W. Reade, Esq. IV. "Notes on Madagascar," by Lieut. Oliver, R.A., at 8.30 p.m.
Tues.—*Inst. Civil Engineers.*—I. Discussion upon Mr. Hawkshaw's Paper "On the Middle Level Drainage." II. "The Charing-cross Bridge," by H. Hayter, Esq., at 8 p.m.
Royal Inst.—"On Sound," by Prof. Tyndall, at 3 p.m.
Wed.—*Soc. of Arts.*—"On the Varieties of Minerals used Economically, considered in reference to their Geological Position, and Relative Value for certain Purposes," by D. T. Ansted, Esq., at 8 p.m.
Thurs.—*Antiquaries.*—At 8.30 p.m.
Royal Inst.—"On Geology," by Prof. Ansted, at 3 p.m.
Royal Soc.—At 8.30 p.m.
Fri.—*Architectural Assoc.*—Special Business Meeting. A. W. Bloomfield, Esq., will read a Paper.
London Inst.—"On Economic Botany," by R. Bentley, Esq., at 7 p.m.
Royal Inst.—"On Japanese Art, by J. Leighton, Esq., at 8 p.m. Annual Meeting of Members, at 2 p.m.
Royal United Service Inst.—"Venetia and the Quadrilateral," by Bonamy Price, Esq., at 3 p.m.
Sat. — *Royal Inst.*—"On the Science of Language," by Prof. Max Müller, at 3 p.m.

TO CORRESPONDENTS.

The Mechanics' Magazine is sent post-free to subscribers of £1 1s. 8d. yearly, or 10s. 10d. half-yearly, payable in advance. Post orders made payable to Mr. R. A. Brooman, of 166, Fleet-street, E.C.

Advertisements are inserted in the Mechanics' Magazine at the rate of 6d. per line, or 5½d per line for 6 insertions, 5d. per line for 13 insertions, 4½d. for 26 insertions, and 4d. a line for 52 insertions. Each line consists of about 10 words. Woodcuts are charged at the same rate as type. Special arrangements made for large advertisments.

To insure insertion in the following number, advertisements should reach the office not later than 5 o'clock on Thursday evening.

Received.—N. S. H.—H. B.—J. B.—T. B. and Co., Manchester (attended to).—C. W. W.—J. W.—E. C. L.—F. B.

The following have been answered by letter—J. T.—G. S.—J. V. P.—V. P.—W. R. M.—H. P.

W. H.—We would partly refer you to the answer under the initials G. C. A. There are copies of all British Patents at the Free Public Library and at the Royal Institution, Liverpool. The number of the patent you wish to see is 657, year 1862. You could procure it by forwarding 7d. in stamps to Mr. Bennet Woodcroft, Her Majesty's Patent Office, London. A rotating brush for brushing the human head is completely described and illustrated in the specification. We should not like to be the hairdresser using such a rotating brush; it would throw the *dust*, &c., about just as the water is thrown off a mop that is being "trundled."

G. C. A.—You cannot register a mechanical motion, contrivance, or principle, under the Registration of Useful Designs Act. The protection only covers the *shape* or *configuration* of useful articles. In any case such a registration costs nearly £14, and would only afford protection for three years. The only way to secure your invention would be by taking out a Provisional Protection, the Government fee for which is £5. Your invention would thus be pretty well secured for six months, which would give you time to obtain the aid of some person with money. Before, however, taking any further steps in the matter, we would advise you to carefully search whether a similar arrangement to your own has been tried before. From the short hints you give of your idea, we rather think that something similar has been attempted previously. We would advise you to look at Specification No. 1905, year 1857. We believe that this patented arrangement has been tried with some locomotive engines on the Great Northern Railway. It was unsuccessful; it racked itself to pieces. By enclosing 1s. 6d. in stamps to Mr. Bennet Woodcroft, Her Majesty's Patent Office, London, you can procure the specification. In most of the principal towns in this kingdom, however, complete printed copies of all the published specifications are on public view. You do not state your address, or otherwise we would inform you the nearest place for you to get access to the old specifications. You had better write to us again, giving your address, and we will then inform you where you can best see these old patents, as we greatly fear that you have lighted upon what is vulgarly termed "a mare's nest."

R. P. (M. S. and L. R.)—With regard to your first query, we may state that the hydrogen gas explosion theory has itself been exploded long ago. Professor Faraday, in the course of a report, made in May, 1859, to the Board of Trade, wrote, "I am of opinion that—as respects the decomposition of the steam by the heated iron of the tube, and the separation of hydrogen, no new danger is incurred. Under extreme circumstances the hydrogen which would be evolved would be very small in quantity; would not exert greater expansive force than the steam; would not with steam form an explosive mixture; would not be able to burn with explosion, and probably not at all, if it, with the steam, escaped through an aperture into the air, or even into the fire-place." Besides, steam is only decomposed by red-hot iron, when the surface is *bright*; the action ceases as soon as the oxide is formed.—2. In constructing one single apparatus for *experimental* purposes, we do not consider that you would be liable to an action for infringement.—3. Yes. For full particulars we would refer you to the Locomotives' Act of 1861. Your road engine must not emit smoke, under a penalty of 40s. for each day the nuisance is continued. The engine must be attended by two persons, and the speed must not exceed ten miles an hour on a highway, nor five miles an hour within a city, town, or village.—4. The best work on turning is that of Holtzapfel—"Turning and Mechanical Manipulation," by Charles Holtzapfel, published by Holtzapfel and Co., 64, Charing-cross. You may probably get the work second-hand from Spon and Co., Bucklersbury. The work is comprised in six volumes at present, but only three are published; each volume is complete in itself, and costs about twenty shillings. Vol. 2 would probably suit your purposes best. We would advise you to make complete drawings before beginning to make your experimental engine. The number of the specification of Hayes's steam generator is 2776, year 1861; you can get it by writing to Mr. Bennet Woodcroft, Her Majesty's Patent Office, London, enclosing one shilling in stamps.

Correspondence.

◆

OCEANIC CABLES.

TO THE EDITOR OF THE "MECHANICS' MAGAZINE."

Sir,—In the "Journal of the Society of Arts," Feb. 6th, 1863, is a letter written by Admiral Sir Edward Belcher, which I recommend "H. K." to peruse, premising that, as I was present during the soundings referred to therein, I can vouch for the accuracy of the observation. If I had ever had any doubts, from analogical reasoning, on the occurrence of deep water currents, I should then have been satisfied. In the Hydrographical Office are stored up an immense number of such observations—similar in the evidence they give to those from which, in the States of America, Capt. Maury deduced his conclusions, and all pointing to the same great fact of oceanic currents existing above, as well as below, though more rarely below than above.

"H. K." denies the possibility of such currents. I offer him proof of their actual existence. But if, by a non-professional man, as I understand him to be, the opinion—nay, the facts—of our highest hydrographical authorities are to be treated is slightingly as those of Capt. Maury, of course, I can have nothing farther to say; but it seems to me that to disable an adversary's judgment, is a most unsatisfactory way of combating the facts on which he has formed his opinion.

Probably no sailor—certainly no hydrographer—will think of denying that there may be places and times where perfectly still water is to be found from the surface to bottom; but this is the exception which proves the rule. In the many deep-sea soundings which I have either read of, seen taken, or assisted in taking, I have never known of another instance of the line being recovered in the state of that mentioned by Capt. Dayman, though I quite understand that it would be so coiled up, under the circumstances which he describes; but on numberless occasions, after a regular descent at gradually increasing intervals, I have seen and known the line to be suddenly increased in velocity of descent by the effects of an under current. Boats, even ships, have often been carried forward at a considerable rate *against* a surface current by the expedient of sinking an iron pot or other heavy body exposing a large surface one or two hundred fathoms, so as to be acted upon by the stronger under current. This is even a common practice in certain places.

The surface current, if running constantly, or even generally, in one direction, probably causes a reciprocity of motion in the lower body of water to supply the loss. The Gut of Gibraltar is a familiar instance of this motion in a moderate depth.

The law of motion of water may be thus stated. It proceeds from the disturbed portion slowly, but surely, downwards; and as, in the case of such disturbance arising from a gale, the velocity of forward motion decreases in a geometrical ratio, from the upper strata (so to speak) which are first acted upon towards the lower, it follows that the curl or comb of the wave (the white horses, as sailors call them) is rapidly produced and increased. But where, during uncounted centuries, the trade winds have continued their action in one direction, the whole body is eventually set in motion, and the tepid water of equatorial seas flows northward in a steady current, miles deep and hundreds of miles in breadth (the Gulf-stream), to compensate for the abstraction of fluid from the Northern Ocean which must be caused by the N.E. trade.

That this is part of the great scheme of nature—that it has its objects and effects beyond what we can absolutely see or feel—has been rationally inferred from the following, among other methods of reasoning:—It seems that only such action, such interchange by currents, could be sufficient to prevent stagnation. This, if existing, would, we believe, be fatal to that wonderful development of oceanic animalcular life which plays so collectively-important a part in the formation and transformation of the globe we inhabit. It is probable that the very matter which the molluscs and animalcules build up into habitations for themselves, could only be obtained in sufficient quantity by the action of currents pervading the ocean which we suppose, nay believe, to exist. The fresh water rivers abstract from the land, and send into the sea in a state of suspension, precisely those building materials which are required by the little oceanic architects. But they are unable to go to seek them. The currents must bring them their mortar, stone, or cement. Thus we may say that the oceanic currents are the hodmen of the zoophytes who, again, are masons ever engaged in reconstructing the earth.

Are these views too strongly, too fancifully, expressed? Look at the shell deposits of the earth—examine the chalk hills which were once the ocean bed. It is not too much to affirm that to corallines do we owe a considerable proportion of the habitable earth—a proportion which is always on the increase. It is not fancy which places those globigerinæ in the microscopic field—identically alike, whether derived from the chalk of our inland counties or the deep-sea soundings of the Atlantic. I have, perhaps, digressed from my subject; but such are the probabilities of currents and also of the nature of the bottom—both which subjects imperatively demand careful investigation from those who would devise or theorize upon oceanic cables. From such facts we deduce the inference that the bottom of the ocean generally is uniform, soft, and undisturbed.

The opinion of two physicians is generally regarded as conclusive on a diseased frame; but I see that "H. K." is not disposed to admit that two sea-doctors are equally entitled to respect, so I must give a few more of the hundred reasons to which "Old Sailor" happily alludes. I thought, I confess, that when it had been shown that a plan for laying cables near the surface failed in doing more than supporting it at some few points, the idea would be given up.

But "H. K." has shifted his anchorage to the north, and, I suppose, I must follow him thither.

I think it will strike most people as extraordinary, to say the least of it, that a gentleman who firmly believes, and satisfactorily (to himself) proves, that there are no such things as deep-sea currents, admitting at the same time the existence of surface currents, should leave the tranquil depths below and take his cable into the troubled waters above. "Old Sailor" has shown him "why" I was afraid chain or wire would not support its own weight, including barnacles and other attachments, therefore little more need be said on that head. But I also would like to know whether "H. K." thinks it an advantage to encounter the chances of a few thousand icebergs every year; for as some of these float with a proportion of 150 fathoms below to 159 ft. above (See Sir J. Ross's evidence in the Blue Book on Submarine Cables), it is evident that they would be very likely to come across one of his buoys, and tear away buoy, cable, and all. But if I were to adduce the many reasons which occur to any seaman, or even to any telegraph engineer, against such ideas as "H. K." advocates, I should waste your space, tire your readers, and, as far as I am concerned, get thoroughly weary of the argument. I hope icebergs, barnacles, and catenarian strain may prove to be objections tangible enough, if not for "H. K." yet at least for others. I therefore must beg him to excuse my further notice of a proposition which is tenable in no single point of view, so far as I am a judge of its merits.

And now I will devote the remainder of my letter to the pointing out what is, in my opinion, really desirable as regards deep-sea cables. Of the ocean bottom we know amply enough to prove that cables once laid there are likely to be and remain undisturbed, except in volcanic regions, which may be and ought to be avoided. Therefore the problem resolves itself into a consideration of the best means of getting them to the bottom with the greatest rapidity and the least danger. "With the greatest rapidity" means that a quick sinking-cable must be sought and employed. "With the least danger," on the other hand, means that a strong cable—strong relatively—must be secured. Unfortunately, these two are antagonistic. Mr. Duncan's rattan cable is *not* strong relatively to its bulk, though it *is* strong relatively to its weight in water per mile; and the bulk, as it governs this latter quality also governs the rate of sinking, makes it sink slowly. Now this is the very worst quality a cable can have, for it remains longer in danger the longer it is in getting to the bottom.

We accept, it is true, as a necessity, a certain diminution of specific gravity; for without it, the cable would not bear its own weight; but at the same time it is also true that, if we could have the qualities we should most prefer, they would be as follows:—the maximum of strength, the minimum of bulk, and the greatest rapidity of sinking. I hope I may succeed in saving some, who have, I fear, misunderstood the problem, from spending any more time or money over schemes for slow-sinking or floating cables. If any one wanted a floating cable—if telegraphists of any experience, and seamen with any knowledge of this part of their profession did not abhor the very idea—it would be the easiest thing in the world to secure a floating cable with merely a sufficient mixture of manilla hemp; but this is just what we do *not* want—this would increase, not diminish, our dangers and difficulties. Of all the cables which I have yet seen or heard of, Mr. Allan's is the one which most nearly fulfils the mechanical conditions sought for; and, I believe, there are few electricians now who can honestly find fault with its fulfilment of the electrical conditions to be desired. Were it true even, that something in this direction has been sacrificed, the gain in other ways would more than compensate for the loss. I say this as a perfectly unprejudiced observer; for I have no other interest than a scientific one in Mr. Allan's system; but I see that it gives the greatest strength in the least bulk, with rapidity of sinking as a consequence, and that, without any outer plastering, the strength is, and is likely to remain, protected from decay. As for the system of laying which I have long advocated, and which has secured the support of my profession, among whom I reckon men experienced in cable laying—which I may say also, is approved by not a few electricians and engineers—it is equally applicable to any and every description of cable, and therefore it cannot be said that I advocate any special rope; but when it is absolutely certain that the cost of the gutta-percha-covered conducting-wire alone, would, for an Atlantic cable, more than absorb the whole sum hitherto subscribed for the renewed attempt to connect England with America—when we know that £300 per mile for a cable has been not only proposed but entertained as a rational expenditure for so great a purpose—it is a duty which every one owes to the advancement of science to urge, by every means in his power, the method by which the outlay may be brought within more manageable limits; to consider, in every stage of the operations necessary to establish telegraphic submarine communication, how money may be saved, how danger may be eliminated or diminished. It is not necessary to lay expensive cables, if only they be properly treated. It is not by overweening self-confidence that dangers are most likely to be successfully met or combated. We are now, it appears, going to have another great experiment in the Persian Gulf cable. Nine hundred miles of a cable weighing about four tons to the mile, and of an inch and a quarter in diameter, are to be taken in sailing vessels round the Cape of Good Hope, to be deposited in water varying from 30 to 800 fathoms. It is true it can scarcely be considered a deep-sea cable; for, rather than encounter the dangers of the ocean, our land engineers prefer to trust to the tender mercies of the Arabs and the attachment of the corallines, &c.; but I could scarce believe my ears when, after all that has been said in the Blue Book and elsewhere about light cables, I found that we were to lay a cable four times as heavy as the late Atlantic, and also were to lay it out of sailing vessels towed by steamers. At what expense it will be done, may be judged by the fact that the Malta and Alexandria Cable cost, from first to last, nearly a quarter of a million sterling for the ships which carried it alone—the cost of cable making up the rest of a sum of £750,000, which I hope represents the total, on which I have heard 39 per cent. is the gross profit during the past year. I cannot but regret that the working of this cable and all the expenses or receipts connected with it, have not been placed by the Government at the disposal of the telegraphists in particular, and the public in general. Paying as the public do for the mismanagement of the Red Sea Cable, I think the nation, and not any eminent contractors, have the first right to any information about a cable made from national resources.

J. H. Selwyn, Capt. R.N.

INDICATORS AND BOILERS.

Sir,—I have read with much interest the review on the work on the Indicator, in the Mechanics' Magazine, and would wish to make a few remarks on certain portions of it:—

First, I entirely agree with you as to the desirability of thoroughly warming the indicator before using it to trace the atmospheric line, and this is certainly very needful in the case of the ordinary indicators, in which there is such a large mass of metal for the heat to act on, and which, therefore, takes some considerable time to get expanded. Secondly, you state that you "differ with the author" in regard to "great economy having been effected in locomotives by the use of expansion." Now, here I think you are in error, as there cannot be the least doubt as to the great economy obtained by the use of the link in locomotives, in place of the old "gab" arrangement, by which means expansion can be employed, and from that moment coal consumption per mile was reduced nearly 50 per cent., and I think it will generally be admitted that, for their power, locomotives are the most economical engines at work.

I agree with you that a "very large field in that direction is still unexplored by railway engineers;" and it is true that none of the indicators you name can take a card that can be "implicitly relied on." It will, I doubt not, be a satisfaction to all who look for a really true, good, simple, and correct indicator, to learn that such a one has at last been produced, and is now in course of manufacture. It has been tested on high pressure engines with 55 lb. steam making up to 220 revolutions per minute, and it produces most perfect and steady cards which can be implicitly relied on. We are now trying it on a locomotive working express trains up to 55 miles per hour, with steam up to 130 lb., and it works admirably. It seems to me that it cannot fail to give perfectly correct indications at any practicable speed, and when tried in slow speed engines, shows inaccuracies which none of the other indicators reveal.

This is the Richards's Indicator, introduced and patented by Charles T. Porter, and was used by Mr. D. K. Clark for taking the diagrams from the engines at work in the International Exhibition. The remarks quoted on the desirability of frequently using the indicator on all engines are excellent, and also those relating to the "engineer" and "engineman." It is a disgraceful fact that "price" is preferred to "quality" in this respect, and that too, in a question where economy in *pence* can hardly fail to lead to extravagance in *pounds*, which will not, I think, be called a very "business way of doing it." On the Continent all men in charge of engines have to pass an examination to to prove their fitness.

The Gateshead engine-maker is not alone in his ideas as to vacuum, as I have heard of a similar occurrence on a well-known river "over the border," and there are instances where 31 in. of steady vacuum have been claimed!

The remarks as to the inadvisability of the huge exploders called boilers I fully agree with, especially as quality of material, right proportions, careful manufacture, careful use, and good attendance and treatment, are not always to be obtained where they are used.

In regard to the employment of steel for boilers of large size, I am not quite convinced of its superiority to good iron of known reputation, as it would seem that the exposure to high temperature which boilers of all kinds experience, must tend to decarbonize the steel, and this most particularly in those boilers most subject to incrustation, and least carefully attended; therefore, if a light boiler has been made of steel, to carry high steam (higher than the same thickness in iron), and this process goes on, it is a question how long that boiler could be considered safe, and whether there would be the great advantage in using steel, which its superior power of resisting strains, if not otherwise exposed to disadvantage, would lead us to hope for.

Löwe found that "wrought iron long exposed at a red heat to steam, became crystalline, and that even the heat alone produced this effect, without the application of moisture. It is not easy to find the cause of this phenomenon in any chemical property of iron; but, be it what it may, the fact is undoubted that iron long exposed to the action of fire loses its fibrous texture, and becomes brittle and crystalline, and results in a weakening of the tenacity and cohesive force of the metal."

With respect to the remark that there is no governor exact enough for regulating cotton mills, I think the beautiful sensitive governor patented by Silver, and in which, if the speed varies over *one-sixth* or less of the revolution of the engine, it is instantly corrected—and also that patented by Charles T. Porter—must have been overlooked, as it seems to me that they are eminently adapted for the purpose.

Of the desirability of a hard cast iron for cylinders, there can be little doubt, but this is now seldom considered by either buyer or seller in those cases where price is the "governor," which, I may say, is the case always, especially since the market has become flooded with "cheap" engines, and purchasers act on their own responsibility, preferring to buy ready-made, instead of employing an engineer to see things done in a proper manner. As to beam and horizontal engines, the superior patronage bestowed on the latter sufficiently shows the predilection to be superior for its employment, but a badly-made horizontal engine may be worse than an equally badly-made beam engine.

The injector, as at present employed, is neither an economical nor a reliable substitute for a pump. I have seen it stop working with cold feed, and refuse to work with feed at 90 deg., as tried with a thermometer; and where a good feed heater is used, the employment of an injector to work with cold feed may be taken as a loss of from to 5 to 10 per cent. in the working of the engine—a disadvantage which I think cannot be easily overcome.

You remark, "there is *always* a dome" on locomotives; this is only partly correct, inasmuch as all the new engines on the Great Western, and many other lines, have *no* dome, but the steam pipe is perforated with small holes or narrow slots on its upper side for the passage of the steam, and is carried under the top of the boiler to the breeches pipe in the smoke box.

As to the injury done to the metal by the present unscientific manner of punching the rivet holes, and then "drifting" them up when they do not match, there can be no doubt; it is a disgrace to our "practical" men that such a state of things should exist, especially as there can be no difficulty in arranging a machine to drill the holes, and the greater part of the plates in a boiler, in such a manner, as to allow of the greater part of the plates being drilled at once, and so that the holes must come "dead true" to one another. I have seen in a factory in the North a 7 ft. boiler of ⅜ plate in course of construction, where the holes were barely one half open, through possibly one-tenth of their number, and after some chipping and drifting, the rivets inserted, or I should rather say "jammed" in and rivetted over, and each, when "snapped," look a real "Simon Pure!" Certainly, there is great room for improvement here.

Warming the plates before bending, to form the shell of a boiler, is certainly advisable; but dished and other plates would, of course, have to be heated. I believe the plates for the Victoria Bridge, at Montreal, had the holes drilled, and so exact was the work, that a rod might be dropped through a hole in a pile of a dozen or two of plates and pass through each. Where boiler making is a business, it would surely be worth while to ensure the greatest exactness by some such method as I have before hinted at.

Your obedient,

Chas. F. T. Young, C.E.

7, Duke-street, Adelphi, W.C.
April 18, 1863.

Miscellanea.

At the special meeting of the Submarine Telegraph Company it was stated that the business was satisfactorily increasing, and that all the liabilities would be discharged, and a substantial reserve established for the proposed allotment of stock. A dividend at the rate of 4 per cent. per annum was declared; and additional capital agreed to be raised in the manner recommended by the directors.

Foreign journals speak of an invention just produced in Germany—namely, a musical bed, so constructed that, by means of concealed piece of mechanism, the pressure of the body produces the softest harmony, which lasts long enough to lull one to sleep. At the head of the bed is a dial with a hand, which can be placed at whatever hour the person wishes to awake; and at the time fixed the bed plays a march of Spontini, with drums and cymbals, loud enough to wake the soundest sleeper.

The quantity of caoutchouc (india-rubber), in its raw or unmanufactured state, imported into the United Kingdom in 1861, was 57,834 cwts., the value of which was £435,923. Of this quantity, Brazil sends 29,042 cwts.; British India, 14,050 cwts.; United States, 9,251 cwts.; New Granada, 1,202 cwts.; Fernando Po, 1,000 cwts.; and all other countries, 3,283 cwts. The price of this commodity varies from £8 5s. 2d. to £3 8s. 1d. per cwt. Of caoutchouc in its manufactured state, the chief items are overshoes and boots, which show a total of 743,535 lb., valued at £41,311—the price ranging from 1s. to 1s. 6d. per lb. Of that quantity Hamburg contributed 289,079 lb.; Hanover, 291,589 lb.; France, 119,328 lb.; United States, 14,208 lb.; British North America, 15,629 lb.; and all other parts, 4,702 lb. Of other descriptions of this manufacture the quantity imported was 116,611 lb., valued at £12,441, the principal portion whereof came from Hamburg, Belgium, France, and the United States.

It is asserted that the largest carriage manufactory in the world is that of a Berlin company formed for the supply of railways. Last year it is said to have employed 1,552 men, and to have made sales to the omount of 1,815,489 thalers (about £270,000).

"J. W." in a letter says:—"It is very amusing to read the recommendations of our great men, particularly when they lay claims to plans which have been published months before in your magazine. Mr. Fairbairn recommends a belt all round the vessel to protect the hull. Well, you have made that plain by drawings long ago, so that your readers will see that he does not deserve great credit for the idea. Sir Edward Belcher mentions another plan on the same page; he, too, adopts it for his own.

Water-glass in Soap.—In the last number of *Silliman's Journal*, Mr. J. M. Ordway, who has devoted much attention to the composition and application of alkaline silicates, states that a mild silicate (water-glass) is now manufactured in Boston and New York, and has come into very general use among soap-makers. It is used as a substitute for rosin, which had been largely employed in the manufacture of soap, before the blockade of the Southern ports. It materially reduces the cost of soap, and imparts neither colour nor smell to it. About 60 per cent. of the fluid silicate, it is stated, may be mixed with the common materials that are employed for making bar soap. Mr. Ordway says:—"It is certainly quite safe to incorporate twenty five or thirty pounds of liquid water-glass with one hundred pounds of pure oleo-stearate of soda. The compound thus produced has greater detersive power than common soap."

Patents for Inventions.

ABRIDGED SPECIFICATIONS OF PATENTS.

The Abridged Specifications of Patents given below are classified, according to the subjects to which the respective inventions refer, in the following Table. By the system of classification adopted, the numerical and chronological order of the specifications is preserved, and combined with all the advantages of a division into classes. It should be understood that these abridgements are prepared exclusively for this Magazine from official copies supplied by the Government, and are therefore the property of the Proprietors of this Magazine. Other Papers are hereby warned not to produce them without an acknowledgement:—

Steam Engines, &c., 2657, 2658, 2662, 2678.
Boilers and Furnaces, 2626, 2668.
Roads and Vehicles, including railway plant and carriages, saddlery and harness, &c., 2622, 2630, 2642, 2647, 2666.
Ships and Boats, including their fittings, 2611, 2638, 2652, 2663.
Cultivation of the Soil, including agricultural implements and machines, 2614, 2639, 2646, 2669.
Food and Beverages, including apparatus for preparing food for men and animals, 2627.
Fibrous Fabrics, including machinery for treating fibres, pulp, paper, &c., 2616, 2623, 2628, 2632, 2636, 2637, 2650, 2651, 2660, 2665.
Buildings and Building Materials, 2625, 2629, 2644, 2645, 2670, 2676, 2677.
Lighting, Heating, and Ventilating, 2615, 2658, 2664, 2671.
Furniture and Apparel, including household utensils, time-keepers, jewellery, musical instruments, &c., 2612, 2617, 2618, 2620, 2621, 2648, 2653, 2661, 2673.
Metals, including apparatus for their manufacture, 2641.
Chemistry and Photography, 2667.
Electrical Apparatus, 2619, 2675.
Warfare, 2624, 2640, 2649, 2679.
Letter-Press Printing, 2654.
Miscellaneous, 2613, 2631, 2633, 2634, 2635, 2643, 2655. 2659, 2674.

2611. R. Alexander. *Improvements in mariners' compasses.* Dated September 25, 1862.

This invention has for its object the improvement of the mariners' compass, and the parts in connection therewith. The improvements consist of an apparatus so arranged as to counteract the effect of local attraction of the iron or other metals upon the needle of a compass in a ship, a vessel, or other place where the magnetic needle is used, thereby enabling it to obey the terrestrial magnetic influence only; and in the use of alumina iron, iron alloyed with nickel, or other ironide for magnetic compass cards; and also in the use of iron alone or alloyed, for the bowls, runs, hoods, and binnacles of mariners' compasses. *Patent abandoned.*

2612. M. A. F. Mennons. *Improvements in the construction of chair settees.* (A communication.) Dated September 25, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2613. T. Kennedy. *Improvements in taps or valves.* September 25, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2614. F. Tolhausen. *An improved steam cultivator.* (A communication.) Dated September 25, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2615. J. Raywood. *Certain improvements in the construction of gas apparatus for the prevention of fraud, and for economizing the consumption of gas.* Dated September 25, 1862.

This invention consists in directing and regulating the supply of gas to the burner, and the patentee proposes to accomplish the same in the following manner:—Enclosed in an outer casing of any suitable form or dimensions, and of any suitable material, he inserts one or more perforated tubes of zinc, or other material, or of wire gauze or netting, in which he places a solid plate or diaphragm at a proper distance from the bottom of the casting, so that, when the gas comes in contact with or against the under side of the plate, it is forced through the apertures of the perforated tube immediately below the plate into the outer case or socket, and it has then to re-enter or pass through the perforations of the tube above the plate before it gets to the burner or tap, thus breaking the rush of force, but not diminishing the supply, and producing a steady and a better light, and preventing the noise and waste of overdue pressure. *Patent completed.*

2616. J. R. Breach and E. B. Pye Smith. *An improved machine for reducing or equalizing the length of animal or vegetable fibres.* Dated September 25, 1862.

This machine consists principally of the following parts—1, an endless travelling cloth or apron upon which the fibres to be operated on are placed. This cloth or apron carries the fibres forward, and delivers them on to rollers, discs, or wheels made of metal, wood, or other suitable material, over which are placed other rollers or wheels held down by means of springs or weights, so as to compress and hold the fibres. These rollers or wheels are actuated by suitable gearing, so as to advance the mass of fibres, and present them continuously to the edges of circular saws, breakers, or tearers, one of which revolves between each pair of rollers or wheels. These saws or breakers are formed with projections so constructed as to break or tear the fibres asunder (without cutting them), which then fall down into a receptacle beneath. The wheels or rollers, and also the saws or breakers, are placed at suitable distances apart, according to the length of fibre desired, and are capable of being adjusted near to or further from each other, so as to produce fibres of the exact length required. *Patent completed.*

2617. J. Eardley. *Improvements in pitch pipes or tuning pipes.* Dated September 25, 1862.

This invention consists in constructing pitch pipes or tuning pipes by inserting in the usual tube, or the outer case of the same, a sliding or moveable piece or frame, which contains the sounding reed or tongue, so that, when necessary, the same may be removed to clear the reed of dirt or obstructions. At or near the fixed end of this reed or tongue, the patentee places a sliding or shifting piece, termed the regulator, which can be moved to and fro so as to nip or hold the reed or tongue at various points, and thus increase or diminish the length of the free part of the said reed or tongue, and, by the use of scale marks, ensure the production of the note or tone required to be sounded; hence these pitch or tuning pipes can be made to sound any and every one of the notes of the chromatic scale, whether full tones or semi-tones. *Patent completed.*

2618. W. Lea. *Improvements in hinges for French casements.* Dated September 25, 1862.

This invention is described and illustrated at page 252, No. 223 of the present volume of this journal. *Patent completed.*

2619. A. Potter. *Improvements in electro-magnetic engines.* Dated September 25, 1862.

This relates to the means of obtaining electro-magnetic motive power by direct rotary motion, and the engine consists of a fixed circle or band of soft iron bars screwed straight across the inside edges of two or more stout wheels; the widths of these bars are to correspond with the thickness of the covers of the electro-magnets to be used. The distance between each bar is to be double that of the width of the bars themselves, and the number of bars to be used in the circumference of the wheels may vary according to the measurement of the circumference, which measurement must be equally divided by the thick of the cores of the electro-magnets. The axle or shaft of the engine is to be set in bearings supported by standards from the foundation plate, and its centre will be also the centre of the circle bars which form armatures for the electro-magnets attached in radial lines to the centre shaft. The length of the armatures may be varied, so as to allow of several electro-magnets being attached to the shaft, side by side, in the same radial line, and form an engine of greater breadth. There should be three, six, or any multiple of three electro-magnets fixed on the axle, that is to say, such number of radial magnets, although such radius or series may consist, as before stated, of one or more than one magnet on the axle, each in the same plane, and they are to be of such length as to rotate as close as possible to the armatures, but without actual contact. The invention relates also to a break for connecting and disconnecting the electric current. *Patent abandoned.*

2620. P. Wright. *Improvementsin the manufacture of parallel vices.* Dated September 25, 1862.

Here the patentee first constructs a slide-box or receptacle for the slide to work in; this may be made of either wrought or cast iron, and receives a slide-bar, the section of which is similar to that of a piece of T-iron. He then forges or stamps out the two parts intended to form the jaws, one of which is fixed securely on the slide-box, and remains stationary upon it; this jaw is slotted in its lower parts to allow the slide-bar to pass through it; the other jaw is also similarly slotted, but is bolted on to the end of the slide-bar. The grip may be obtained by means of a box and pin in the ordinary way; or the stationary jaw may receive a female screw through which the pin or male screw may work, a collar being fixed on the pin to bring back the moveable jaw. By these means the patentee obtains a perfectly parallel motion with a firm grip. *Patent completed.*

2621. J. R. C. Taunton. *Improvements in the manufacture of metallic bedsteads, cots, and couches.* Dated September 25, 1862.

This consists in making the foot rails with a graceful sweep, curve, or other ornamental line in plan. This the inventor effects by curving or shaping the angle iron or bar forming the frame at the foot into any desired shape; and if he requires to use a solid foot rail upon this frame, it may be made of sheet metal japanned, if requisite, and afterwards ornamented by attaching thereto planted or raised enrichments in various descriptions of metal, papier mache, wood, composition, or other suitable material. *Patent abandoned.*

2622. E. G. Muntz. *An improvement or improvements in the manufacture of axles.* Dated September 25, 1862.

This consists in employing cast and wrought iron or steel in combination in the manufacture of axles. The inventor takes for the arm or centre of the axle a bar or faggot of wrought iron or steel, around which he casts iron or steel. *Patent abandoned.*

2623. T. R. Harding. *Improvements in machinery for opening, cleansing, and carding fibrous materials.* Dated September 25, 1862.

This relates—1, to apparatus for opening, cleansing, or preparing fibrous materials. The material is placed upon a travelling feeding sheet, which delivers it to the first of a series of porcupine rollers. Each of these rollers has its pins set in a direction contrary to that of its motion, and an increased speed is given to each of the rollers of this series of the roller immediately preceding it. Thus, the second roller on to which the material passes has an increased rapidity of revolution as compared with the first roller. In like manner, the third revolves more rapidly than the second: and so on through the series. Under each of these rollers (which may be heated) is a dish, trough, or plate of the same sweep or curve as the curve described by the points of the pins during the revolution of the rollers. The inner surface of the dish, trough, or plate approaches nearly to the points of the pins, but openings may be made in various parts of the dish, trough, or plate so as to allow any waste tow, or any impurities or foreign matter to fall through. Between each porcupine roller the plates, dishes, or troughs are joined, and when the material is taken from one roller to the other, it is drawn out a little by the greater speed of the roller which takes it up. The fibrous material is then taken from the last roller by any of the ordinary mechanical arrangements now in use for the purpose. The invention consists—2, in a mode of constructing circular card cylinders, whereby they can be made lighter and at less cost than those now in use, and so that the dust and other impurities may be removed from the fibres with facility. *Patent completed.*

2624. W. Pettet. *An improved covering for protecting vessels and forts from shot, shell, and other warlike missiles.* (Partly a communication.) Dated September 25, 1862.

This consists in covering the exposed parts of the structure to be protected with an armour composed of boiler-plate iron and an intermediary elastic filling. *Patent abandoned.*

2625. J. J. Bates. *A new or improved window sash fastener or guard.* Dated September 25, 1862.

This consists in so arranging certain levers and springs in connection with plates of metal having holes therein that a window sash, when shut down, may with facility be fastened, and when partly open, may be retained in that position, and prevented from being raised from without. *Patent completed.*

2626. E. Dixon. *Improvements in machinery and furnaces used in the manufacture of welded iron tubes.* Dated September 26, 1862.

This relates to the simultaneous welding of two tubes; and the distinctive features of this invention are the use of a single or ordinary draw-bench, instead of a double or compound draw-bench, and the building of the furnaces separately or wholly independent of each other. *Patent completed.*

2627. C. D. Abel. *An new or improved purifying or preservative lotion for the mouth.* (A communication.) Dated September 26, 1862.

Here the inventor mixes together one ounce of the following ingredients:—Cochlearia, vine tendrils, rose leaves, pyrethrum, pounded Peruvian bark, earth moss, and scraped horse-radish; to these he adds thirty-two ounces of alcohol of 18 deg. strength, and thirty-two ounces of distilled water. This mixture is then allowed to stand for about a fortnight in a warm place. At the end of this time he adds one ounce of the root of anatherum and one ounce of pounded cloves, and again lets it stand for another fortnight or three weeks, shaking it frequently during that time. The fluid portion of the mixture is then separated by filtration, and to this is added two ounces of tincture of myrrh, two ounces of tincture of guajaci, and two ounces of tincture of cinnamon. The lotion is then bottled for use. *Patent completed.*

2628. J. Milner, R. D. Milner, and F. Hurd. *Preparing fibrous substances.* Dated September 26, 1862.

This consists in regulating the drag in the passing of the sliver of wool or other material from the front drawing roller to the bobbin by means of friction discs, in substitution for the apparatus ordinarily employed for that purpose. *Patent completed.*

2629. W. E. Gedge. *Improvements in the construction of leaden window sashes, casements, or glazed coverings or partitions.* (A communication.) Dated September 26, 1862.

This consists in forming in the leaden sashes small holes or openings for carrying off the condensed vapour which forms on the inside of the glass. *Patent completed.*

2630. W. M. Cochrane. *Improvements in securing the bolts and nuts of railway fish plates.* Dated September 26, 1862.

Here the inventor retains the screw nuts—and also the screw bolts when they are not otherwise held from turning—by employing plates of thin metal between the fish plates and the screw nuts, and also between the fish plates and the heads of the screw bolts, when the screw bolts are not otherwise prevented from turning. These thin plates have two holes through them to admit of the two screw bolts near the end of a fish plate passing through them. The thin plate is of sufficient length to extend beyond the two screw nuts which fasten one end of a fish plate to a railway bar, so that when the screw nuts have been screwed tightly, the ends or the angles of the thin plate are turned away from, and at right angles to, the fish plate, so as to come against one or more sides of each of the screw nuts, by which the nuts will be securely held and retained from turning after being once well screwed up. In like manner a similar plate is placed between the two heads of the two screw bolts, which are used to fasten one end of a fish plate to a rail when such screw bolts are not otherwise prevented from turning. *Patent abandoned.*

2631. F. R. Stack. *Improvements in escalading apparatus for military purposes.* Dated September 27, 1862.

This invention consists of a platform of splayed timbers, mounted at one end upon travelling wheels, behind which there is a guiding lever with stay irons jointed to the platform. Upon the timbers is placed a series of planks or treads at a short distance from each other, for crossing moats or ditches (the inner side of which is not much higher than the outer one); the apparatus is thrown across intact. But for scaling walls, which require the apparatus to be elevated to an angle of more than about 30 deg., every alternate tread is removed so as to form a ladder. For passing over low walls or pales, two platforms are jointed to a central piece, the whole being kept straight by ropes passing over stanchions. After being placed in position, the ropes are cast off, when the central piece takes a bearing upon the top of the wall or stockade, and the inclined platforms afford the means of ascending on the one side and descending on the other. *Patent abandoned.*

2632. J. Crosby. *Improvements in carding engines.* Dated September 27, 1862.

This invention consists in an improved arrangement for removing the impurities from the fibrous materials during the process of carding. Under each working roller the inventor places a sheet of metal, or other suitable material, in such manner that it receives and conveys the impurities which are thrown off to the floor or other desired place or receptacle. *Patent abandoned.*

2633. H. Hutchinson. *Improvements in machinery for covering wire with india rubber and gutta percha, and similar gums and compounds thereof, and for manufacturing tubes and other articles of such gums and compounds.* (A communication.) Dated September 27, 1862.

The main object of these improvements is to effect the covering of wire of any length with india rubber and gutta percha, and their allied gums or compounds thereof, and the manufacture of tubing of any length of such gums or compounds by an uninterrupted operation. The principal portion of the machinery to which the improvements relate consists of a screw working in the bore of a cylinder, into which the gum is fed, and from which it is forced by the screw through or into a die of the necessary size and form to produce the exterior of the covering tube or other article to be produced. *Patent completed.*

2634. M. Henry. *Certain new and improved applications of petroleum and its products, certain agents produced by combining the same with other substances, and certain modes of treating caoutchouc, gutta percha, and their compounds, and substances similar thereto.* (A communication.) Dated September 27, 1862.

This invention relates to the employment of petroleum and its products for vulcanizing and devulcanizing caoutchouc for producing certain agents or compositions, and for other manufacturing and useful purposes. In carrying out the invention, a particular product or mixture of petroleum (called mixed petroleum) may mostly be employed with advantage. This product or mixture consists of a combination of the three following products, obtained by distillation or rectification from the clear and very volatile petroleum generally procured from America, though it may be from other places: -1, a clear colourless liquid, boiling at about 154 deg., smelling like ether, and of the density of 0·669 deg. At 60 deg. the density of its vapour is 3·05 deg. This liquid, which is the most plentiful product of distillation, is called (especially by Pelhouze and Cahours) hyduret of Caproylene. 2, a clear, colourless, strongly-smelling etherated liquid, distilling at about 203 deg. 3, a heavier, clear, colourless liquid, distilling at about 310 deg. By combining these three products, the compound which is called mixed petroleum is obtained. A principal object of the invention consists in the application of petroleum as a solvent. *Patent completed.*

2635. J. C. P. Bauchard. *A twice-transversal kneading trough.* Dated September 29, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2636. H. Brum. *Improvements in the manufacture of moreens and such-like fabrics.* Dated September 29, 1862.

The object of these improvements is economy of manufacture by the introduction of jute yarn therein, as a substitute for worsted yarn, for the weft in the manufacture of such fabrics. *Patent abandoned.*

2637. J. Brown. *Certain improvements in carding engines employed for carding cotton and other fibrous substances.* Dated September 29, 1862.

This invention relates to that portion of the carding engine known as the doffer, a principle feature therein being the ready adjustment of the doffing comb or knife. The improvement consists in the novel method of imparting an adjustable rocking motion to the shaft to which the doffing comb is secured, which is effected as follows:—A slotted tail piece or quadrant is keyed upon the rocking shaft, and is connected by means of a connecting rod with an eccentric or crank driven by band and pulley, or other means, the connection with the slotted quadrant being effected by screw and nut rack and pinion, or other equivalent means, by which the position of the connecting rod may be adjusted in the slot of the tail piece or quadrant, so as to lengthen or shorten the curvilinear motion or course thus given to the doffer as required. *Patent completed.*

2638. R. Griffiths. *Improvements in the construction of iron ships and in the method of fastening metal sheathing thereon to keep them from fouling.* Dated September 29, 1862.

This invention consists in having slips or bars of iron or other suitable metal secured with screws or rivets along the longitudinal joints of iron ships, having rabbets or recesses on each edge of them, so that strips of wood or other suitable material can be inserted so as to caulk and secure the joints, and keep the water from coming in contact with the joints and rivets, or passing through the joint in the skin of the ship. When the ship is built with one row of plates lapping over the other, or what is generally termed "clinker-built," the ships or bars in that case will only require to have the rabbets or reccases on one edge, the recess on the other edge being formed by the bars being placed as much over the edge of the plate as will be required for the wood or other caulking material to be inserted. When the iron ship is to be sheathed with metal sheathing, the patentee coats over those parts which are to be sheathed with marine glue, or other suitable adhesive material that is a non-conductor of electricity, and also the metal sheathing, which may be sponged over with an ordinary suitable solution such as is used for marine glue; or the sheets of sheathing may be made hot (to make them and the non-conducting materials stick together) just before the sheathing is put on; it (the sheathing) is then nailed along its edges to the wood or the material that is in the rabbets or recesses of the iron strips along the joints of the ship. When the iron plates in the skin of the ship are wider than it would be desirable to have the sheathing sheets, he then puts longitudinal strips of iron with a recess on each edge of them for inserting the wood in along the middle of such plates to secure the sheathing to. When the sheathing is secured to the strips of wood that are in the recesses of, or formed by the iron strips or bars, he then covers the strips or bars with sheathing metal nailed to the wood strips along the edges; or the longitudinal strips or bars may be covered with a thicker metal than the sheathing, so as to clip the edges of the sheathing sheets, and secure the wood strips in the recesses of the longitudinal bars. The strips of covering metal he proposes to secure to the wood strips by metal screws, so that they can be readily removed when the sheathing is to be replaced. In such iron ships where it is not necessary to caulk the joints, as already stated, he puts longitudinal narrow cleats of wood, at suitable distances, to which he nails the sheathing in a similar way to that described when iron strips with wood inserted on each side are used. *Patent completed.*

2639. M. Puddefoot. *Improvements in apparatus for tilling land.* Dated September 29, 1862.

This invention consists of a truncated cone forming the body of the instrument; this is mounted on an axis and in a suitable frame, so as to turn in a rolling direction while passing over the ground. The frame is furnished with handles to guide it like an ordinary plough, and a beam or part to apply the tractive force. On the cone piece or body at the large end, the inventor applies in radial positions what he terms curved coulters or tines, sharp on the one edge, and thick on the other edge or back, and on the other end he mounts, in a similar and radial position, a series of what he terms shares, being spade-like instruments which are set at an angle to the axis, and so as in revolving to throw the soil on one side, that is, in the direction of the length of the axis, so as to form a furrow. This implement, in rolling over the ground, causes the tines or coulters to enter and stir up the soil, while at the same time the spades or shares forms the furrows. The tines or spades act on different parts of the soil at the same time, the tines during the one traverse of the implement loosening and lightening the soil operated on in the subsequent traverse of the spades. *Patent abandoned.*

2640. W. B. Lord. *Improvements in loading firearms, and in blasting.* Dated September 29, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2641. W. E. Gedge. *An improved furnace for casting steel.* (A communication.) Dated September 29, 1862.

This improved furnace (which is more especially intended to cast steel in large masses) is composed of a crucible or basin of reception, with a moveable cover or lid at its upper part, and at its lower part an opening, called the tapping-hole, of a fire-place beneath the crucible, with doors, grating, and ash-pit or pan. On issuing from the fire-place the flames embrace all parts of the crucible, and gain the chimney-piece above. A little above the crucible is an opening for inspecting the working, and at the bottom of the fire-place are conduits or blast pipes for increasing the draught. The ash-pit, the fire-place, the crucible, and part of the chimney are surrounded by refractory brickworks, which are in their turn enveloped in the ordinary brickwork which forms the exterior of the furnace. *Patent abandoned.*

2642. J. E. Walker. *Improvements in signalling on railways.* Dated September 29, 1862.

This invention consists in, or has reference to, signalling from a station or other place on the line of railway by sounding a whistle or alarum (or a bell) attached to the engine, or other point of the train, if desired, and for which the inventor prefers to use the following arrangements:—He places a post or standard at the side of the railway, and sufficiently near to the rail for the purpose hereafter mentioned, the said post being provided with a moveable bar, arm, lever, or projecting piece attached thereto, to which is connected a wire, chain, or cord passing over pulleys, and carried to a station or point where a railway attendant can, by actuating the same, move the said moveable bar, arm, lever, or projecting piece when required to signal, and whereby the same may be brought back again against the post or standard when the position at rest is required simply by the attendant adopting a reverse movement. The said bar, arm, lever, or projecting piece is to be so much elevated above the height of the rail that it shall be in a position to lift or act upon a moving bar, arm, lever, catch, or projecting piece attached to the front of the engine, or to other point in the train of carriages, and by such lifting or acting upon the said bar, arm, lever, catch, or projecting piece will thus act upon arrangements consisting of a chain, wire, or cord passing over pulleys and connected at its other end to the handle or tap of the steam whistle. Or these arrangements would set a-going the alarum or bell, and sound the same when connected with such arrangements. *Patent abandoned.*

2643. H. Hirsch. *Improvements in apparatus for showing combinations of colours.* Dated September 29, 1862.

This invention relates to the production of combinations of colours by giving coloured surfaces rapid rotation, and consists—1, in a mode of producing the rotation for this purpose by the employment of certain twisted strings (as described); 2, in a mode of causing the rotation of discs or other figures with various colours, patterns, or perforations to be retarded, and accompanied by vibratory motion, by means of portions turned up so as to be resisted by the air (as described). *Patent completed.*

2644. H. Moule. *Heating frames and the beds of hot-houses.* Dated September 29, 1862.

In order to heat the beds of frames and hot-houses in which pots containing plants are placed, or which contain the earth in which the plants are growing, or where moist heat is required for other purposes, the inventor forms below the bottom of the bed a chamber kept constantly or as often as required supplied with steam; the steam is intro duced into the chamber from a boiler. Below the steam chamber is another chamber equal in extent to the bottom of the bed or frame, into which the smoke from the stove which generates the steam is at once admitted on leaving the stove; this chamber is also provided at another part of it with a chimney or flue to permit the smoke to pass away. In order to heat hot-houses and other buildings used for growing plants or for other purposes, he forms an air chamber below the floor of the building, the air chamber being equal in extent to the floor. Below the air chamber is a smoke chamber, also equal in extent to the floor into which smoke is admitted from a fire-place or furnace, and allowed to pass away through a flue or chimney. The air in the air chamber is thus heated, and gratings or openings are formed in the floor which permit the heated air to escape into the building. *Patent abandoned.*

2645. H. Ellis. *Improvements in the manufacture of compounds of silica, and in the application of certain compounds of silica to mineralize woven fabrics, paper, and paper pulp, to harden and preserve stone and cement in the production of artificial stone and paint, and in the production and glazing of porcelain and such like manufactures.* Dated September 29, 1862.

To manufacture compound silicates, the patentee first precipitates the compound silicates out of solutions of silicate of soda, or of potash, by means of solutions of any of the salts of the metals, or of the earths. He then strains and washes the silicates so obtained; and while recently formed, or in the gelatinous state, he redissolves them in as much as may be sufficient of a solution of silicate of soda, or of potash, or of both. If the silicates have been allowed to get dry, he heats the mixture up to the boiling point to facilitate their solution. All gelatinous silicates, however obtained, may be made soluble in the above manner, and by addition of carbonates of soda or of potash. Solutions of the boro-silicates, phospho-silicates, and chromo-silicates he obtains by mixing saturated solutions of borate of soda, or chromate of potash, with an equal quantity by measure of solutions of silicates of soda, of potash, or of both, of about 1·2 specific gravity, and then precipitating by means of solutions of the metallic or earthy salts, and washing and redissolving the recent precipitates so obtained in the manner described. All the above compound soluble silicates may be reduced by evaporation into a gelatinous state, and preserved for use in that state in air-tight vessels. *Patent completed.*

2646. J. Bucknall. *Improvements in the construction of horse-hoes.* Dated September 29, 1862.

In this improved horse-hoe the patentee uses a cranked axle for the running wheels, and on any convenient part of this cranked axle is secured a worm wheel, into which gears a snail or worm, so that, by actuating this latter by means of a handle or lever adapted to its shaft, the cranked shaft may be turned round on its bearings, and by that means be raised or lowered, thereby raising or lowering the entire framework of the implement with the tines and other parts attached to the frame. The tine-bar is placed immediately below the cranked axle of the running wheels, and the tine levers are mounted on a round bar or shaft in front of the running wheels, the tine levers being secured thereon by means of tightening screws, so that their position on the round shaft may be altered and adjusted for the purpose of raising, lowering, or regulating the inclination of the points of the tines either in or out of the ground. In order to take the strain off the tine bar, draught-bars are adapted to the latter, and connected at their opposite ends to the shafts. The front round lever bar is suspended by links from two slotted bearings fixed to the framework of the implement, so that the front lever bar, and with it the lever and tines, may be moved laterally in either direction by means of a hand lever, which turns on a central pin as a fulcrum, its outer end being connected to both of the ends of the round front bar of the implement by means of suitable links and screw couplings. *Patent completed.*

2647. J. Addison. *Improvements in moorings or apparatus for securing articles, applicable also to the fixing of chairs for railways.* Dated September 29, 1862.

This invention consists in the use of plates of metal, of sizes proportioned to the strain likely to be exerted upon them, which are placed in pits made in the earth for their reception, prepared with a bottom of loose earth on which the plates rest, and into these pits, after the placing of the plates, sufficient water is admitted to lower the plates to create a perfect atmospheric pressure. *Patent completed.*

2648. R. A. Brooman. *Improvements in saddle-trees and collars.* (A communication.) Dated September 29, 1862.

This invention consists in making the sides of saddle-trees of several light pieces of wood united together, and with a space between the sides, which space is covered with leather, and the whole tree made as hereafter described. The two side frames are made of several thin flat pieces of wood, united in front by a curved piece of like material to fit over the withers of the horse, and by a similar piece for the back with the addition of the back pummel. The whole of the lower surface of this frame is covered with damp leather, which is bulged out between the side frames, and secured at the edges by pins; a wooden form is temporarily wedged in between the side frames to cause the leather while being dried to assume an arched form. When the leather is partially dry, it is cut and trimmed and sewn to the side frames; strips of leather are fitted all along the side frames and to the pummels, and the drying is completed in a stove or otherwise. A metal bow is rivetted or screwed to the front of the side frames passing over the arched leather; further back stirrup loops are attached, as also rings or other like additions, and the saddle-tree is complete. In the construction of collars, the inventor uses a strong wood mould made in one or two parts, with a metal flange secured to it, on which leather is laid. The leather is damp, and maintained to the shape of the mould by cords passing through holes formed in the flange. When dry, the mould is removed, and the rigid form of the leather is retained by a metal piece passed round its outer surface, and by a strong leather band by its inner surface, and the flange is consolidated by cords passing through holes in the metal piece, as well as round the leather band. The curvature of the leather is maintained by a piece of wood fitting under the cheeks. Thick padding is placed at top inside the collar, which is stuffed with straw, hair, or other material; outside the cheeks, and below the cheeks, there is a packing of felt, hair, caoutchouc, or other material, the whole being covered with leather. *Patent completed.*

2649. J. H. Johnson. *Improvements in shells for war purposes.* (A communication.) Dated September 29, 1862.

This invention relates to either spherical or elongated shells, and consists, firstly, in forming the main cavity of the shell by using a core of the form of a regular or nearly regular polyhedron, so as to leave the cavity with several plane or nearly plane faces, forming angles or corners at the junctions of these planes. By these means the shell is ruptured at each angle, and breaks into as many parts as there are planes in the walls of the cavity. Another improvement consists in causing the fuse-plug or tube to extend back into the centre of the cavity, thereby ensuring the firing of the charge at the centre of the shell first. This end of the plug is made of thinner metal, so that it will collapse and close so soon as it is acted upon by the explosion of the charge, thus preventing any loss of gas through the fuse. *Patent abandoned.*

2650. W. Carrick and W. Carrick, jun. *Improvements in felting apparatus.* Dated September 29, 1862.

This invention relates to a peculiar construction and arrangement of apparatus for planking felt hats and other goods, and consists in the use of a vessel with curved ends for containing the hats or other goods in process of felting, which vessel is fitted with one or more moveable or vibrating presses, suspended from a single point above, so as to cause them to describe an arc of a circle; or they may each be suspended from two points of oscillation, as may be found most expedient in practice, for giving a pressure and causing a continual revolving motion of the goods under treatment. The stroke or the size of the pressers may be varied, either by adjusting the length of the cranks which impart the vibrating motion thereto, or moveable pieces may be added to the faces of the pressers themselves, so that the pressure is always regulated to the bulk of the goods. *Patent completed.*

2651. R. Hoyle. *Improvements in machinery or apparatus for printing surfaces of woollen, mohair, cotton, and other fabrics.* Dated September 30, 1862.

This invention is not described apart from the drawings. *Patent abandoned.*

2652. E. J. M. Le Breton. *An improved propeller for boats and ships.* Dated September 30, 1862.

This propeller may be worked by manual labour, steam engine, or other power, and may be fitted to any part of a boat or ship, and two propellers—one fitted at the stern to push, and the other at the bow to pull—may be advantageously worked together. The propeller itself consists of two flaps hinged to an upright in such a manner as to expand and expose the whole surface of the flaps when being driven in one direction, and to collapse and afford little resistance on being drawn or driven in the reverse direction. The upright to which the flaps are hinged is connected to rails protruded horizontally from the boat or ship on which it is free to travel to and fro. The upright is prolonged upwards for the reception of a shaft, to which to and fro motions are communicated by hand, steam engine, or other power. The upright is capable of oscillation for the purpose of causing the propeller to steer as well as propel. *Patent abandoned.*

2653. J. L. Hughes. *Improvements in producing ornamental patterns in gold and colour on porcelain, earthenware, glass, and enamel.* Dated September 30, 1862.

When producing ornamental patterns in gold on porcelain, earthenware, glass, or enamel, the patentee covers the whole surface of the article, or such part or parts thereof as is, or are intended to be, ornamented with gold, which he applies in the manner ordinarily practised by glass and china painters, and which is well understood, and he burns it on to such surface or part or parts thereof where the ornamenting is to be produced. On to the surface or parts thereof so coated with gold, he places a printed impression, taken by preference on paper from an engraved plate, or from other printing surface, such impression being taken in a bituminous or other varnish which will resist the action of acid. The impression is to be transferred on to the surface of gold and the paper removed therefrom, as is well understood in transferring impressions on china and glass. When the impression is set, he applies a liquid which will dissolve or loosen the gold where it is unprotected by the varnish of the impression. For this purpose he uses aqua regia, or fluoric acid—the acid should be diluted in the proportions of about one of acid to one of water—and in this manner the ornamental device or pattern is produced. *Patent completed.*

2654. A. Prince. *Improvements in the manufacture of varnish, printing ink, paint, and printing colours.* (A communication.) Dated September 30, 1862.

This invention consists in the use and application of petroleum, or the products thereof (instead of linseed oil hitherto in use), to the manufacture of varnish, printing ink, paint, and printing colours, and oil colours of every kind. Instead of natural petroleum, coal and schist oil, prepared in an artificial way, may likewise be applied. *Patent completed.*

2655. J. Wright. *An improved rotative travelling crane.* (A communication.) Dated September 30, 1862.

This invention is carried out as follows:—On a stand or framing of suitable weight and strength, the inventor places an engine and boiler, which, through a pinion on the main shaft, gives motion to a large cog wheel fastened on the spindle of the drum, on which is coiled the chain passing from it to the extremity of the jib, and terminating in a hook or its equivalent in the usual manner. A tie rod passes from the extremity of the jib to the extreme rear of the machine, by which means the weight of the boiler, engine, and the machinery counter-balances the weight of the substances or materials to be lifted. The whole apparatus turns on a circular rail round a pivot supported on a frame. The operation is as follows:—The chain is made fast to the substance or weight to be lifted, and the engine being put in motion coils the chain round the barrel or drum, thereby hoisting the weight. When it has been raised high enough, the crane is turned round on the circular rail before-mentioned by means of a steam cylinder mounted on the framing, and connected by means of toothed gearing with the axles of the wheels. When not in use, the crane can be transported from place to place by means of wheels which can be raised or lowered by the action of a screw, and when not in use they may be drawn up out of the way of the circular rail. *Patent completed.*

2656. G. Haseltine. *Improvements in warming and ventilating buildings.* (A communication.) Dated September 30, 1862.

This invention consists, mainly, in an arrangement for warming to a moderate and pleasant degree the floor and lower part of the walls, when necessary, in connection with an arrangement for the admission and general diffusion at or near the floor of air warmed only to the temperature at which it is wanted for respiration (say fifty or fifty-five degrees, more or less), by being made to pass in contact with a very large non-metallic warming surface, kept at a moderate temperature, a temperature not higher than that to which nature warms the earth's surface in summer. This fresh air, being admitted at a temperature a little lower than the general temperature of the air in the room, will remain in the lower part of the room, where it is wanted for respiration, and not ascend at once to the ceiling (where it can neither be heated nor serve for warming), as is the case with highly heated air from steam pipes and hot water pipes, as well as from furnaces and stoves, thus wasting the heat upon the ceiling and upper parts of the room, and forcing the foul air (which should be the lightest air in the room and rise uppermost) downward to be inhaled. *Patent completed.*

2657. P. G. V. Byl. *A power conserver brake for utilizing the power expended in stopping or retarding machinery, locomotive or other engines, and vehicles of any description when in motion.* (A communication.) Dated October 1, 1862.

This invention consists in constructing apparatus for stopping or retarding machinery, locomotive and other engines, carriages, trucks, vans, and vehicles of any description used on railways or on common roads, in such a manner that the power which is expended by such stopping or retarding is accumulated or stored up by the apparatus, and given out again by the same when it is required to start the machines, engines, or vehicles again, so as to assist them in their motion. The arrangement of apparatus for carrying out the principle of this invention admits of various modifications to suit the particular machines, engines, or vehicles to which it is applied. *Patent completed.*

2658. R. W. Greenwood and C. J. Marson. *A new and improved mode of using the exhaust steam of steam engines by reconveying the same into the boiler.* Dated October 1, 1862.

This invention is not described apart from the drawings. *Patent abandoned.*

2659. B. Donkin. *Improvements in bearings for shafts, axles, pivots, and sliding surfaces for the purpose of diminishing friction.* (A communication.) Dated October 1, 1862.

This invention consists in providing a water or liquid bearing for shafts, axles, pivots, and sliding surfaces by a continuous circulation of liquid forced between a metal box and the shaft, axle, pivot, or sliding surface, so as to prevent contact of surface with surface, whatever be the material constituting such surfaces. The inventor takes a box or case shaped to correspond with the shape of the revolving or sliding surface to be used with it, and forms therein a central cavity followed by several concentric, quadrangular, or other cells, according to the surface. He makes an orifice in the central cavity to allow of the inlet of water or other liquid under pressure. *Patent completed.*

2660. E. Lord. *An improvement in power looms for weaving.* Dated October 1, 1862.

This invention is not described apart from the drawings. *Patent abandoned.*

2661. W. C. Cambridge. *Improved apparatus for washing clothes, applicable also as a churn.* Dated October 1, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2662. J. Gilchrist. *Improvements in boring engines such as are used for mining purposes.* Dated October 2, 1862.

In one modification of this improved engine, the principal parts are fitted upon a framing which is by preference mounted upon wheels. The parts comprise a steam boiler, winding details, with actuating cylinder or cylinders, and a cylinder for imparting the required reciprocating motion to the boring rods. This last-mentioned cylinder—which may be fixed or oscillating—is disposed horizontally, and its piston rod actuates the vertical arm of a bell crank lever, centred on a fulcrum or on journals at a higher level than that of the cylinder, and having its other arm projecting horizontally outwards over the bore, and being connected to the boring rods. The steam may have access to both sides of the piston, its action on both sides or on one side only being regulated by a suitable valve actuated by hand or by the movement of the piston rod itself; or the steam may be allowed access to only one side of the piston. The arms of the bell crank lever need not in all cases be at right angles to each other, but may in some cases be arranged to suit a diagonal or inclined position of the actuating steam cylinder. When the boring rods have to be drawn out of the lever, the bell crank lever may be disconnected and turned out of the way. *Patent abandoned.*

2663. W. H. Ward. *Improvements in night, day, and fog signals, and in the means for effecting the same.* Dated October 2, 1862.

This invention is not described apart from the drawings. *Patent completed.*

2664. W. C. Wilkins. *Improvements in gas-burners.* Dated October 2, 1862.

This invention relates, partly, to an adaptation or combination of parts when using burners formed of two or more concentric rings perforated for the escape of the gas for combustion. Each ring of the burner is supplied from a separate reservoir or chamber through two or more branch passages, which branch passages vary in number with the size of the ring with which they communicate, and each of such reservoirs is supplied by a separate pipe or channel with a tap or valve adapted to regulate the quantity of gas for the time to be supplied to such reservoir. By these means the quantity of gas supplied to any part of the respective rings is rendered uniform, and that to any one ring is capable of being regulated in relation to that supplied to the other ring or rings. The inventor applies with such burner a glass chimney contracted somewhat at a distance a little above the burner rings, and he applies adjusting means to adjust the height of such contracted part; he also applies fine wire gauze or other fine reticulate open work to regulate the supply of air upwards to the burner, and he applies a fence between such reticulate open work and the glass chimney. *Patent abandoned.*

2665. E. Suckow and E. Habel. *Improvements in machinery for preparing, spinning, and doubling fibrous materials.* Dated October 2, 1862.

This invention relates to mechanism for twisting a sliver or thread, and at the same time winding it upon a bobbin; and it consists in a combination and arrangement of mechanism by which the bobbin is simultaneously rotated upon its own axis, so as to wind and distribute the thread upon it, and revolved in a plane passing through its axis to put the twist in the sliver or thread. *Patent abandoned.*

2666. J. H. Johnson. *Improvements in the permanent way of railways.* (A communication.) Dated October 2, 1862.

This invention relates to an improved form of railway chair and construction of joint for the rail ends, and consists in casting the upright jaw of the chair which is on the inside of the rail separate and distinct from the plinth of the chair, and of a wedge form. The outer jaw is cast on the plinth in the usual manner, and the upper part of the plinth on the inside of the rail is made with a raised tablet which acts as a butt to the wedge jaw which is inserted between it and the rail, thereby firmly holding the rail in its position. This wedge jaw is locked by a screw bolt passing through it and the plinth, and screwing with one oblong wrought-iron nut inserted on the under side of the plinth. When stone block sleepers are used, the chair plinth at that part upon which the rail rests is made to receive a cushion of lead or other suitable material, thus preventing immediate contact between the rail and the upper part of the chair plinth. This lead or other cushion is retained in its place by the moveable jaw of the chair; the chair itself is secured to the stone block by the screw bolts passing up through the stone and the plinth of the chair, and a nut screwed on above. *Patent abandoned.*

2667. G. J. Firmin. *Improvements in the treatment of certain salts of potash and lime.* Dated October 2, 1862.

This invention consists in utilizing the waste liquors arising in the manufacture of tartaric and citric acids, to obtain therefrom suitable products, as follows:—The usual method of manufacturing tartaric or citric acid is to saturate bitartrate of potash or lemon juice with bicarbonate of lime, and to treat the resulting tartrate or citrate of lime with sulphuric acid to obtain the tartaric or citric acid. According to this invention, the patentee recovers the tartaric acid contained in the liquid, and this he does by adding to it sulphuric acid. *Patent completed.*

2668. F. Ensor. *A new or improved apparatus for regulating the pressure of steam in steam boilers, and for indicating when the water in steam boilers is too high or too low.* Dated October 3, 1862.

We cannot here give space to the details of this invention. *Patent abandoned.*

2669. J. Harrop and J. Wadsworth. *Improvements in deodorizing refuse, organic, fecal, and urinous matters, and in a method of utilizing coal and other ashes, and in machinery or apparatus connected therewith, for producing a portable manure therefrom.* Dated October 3, 1862.

This invention consists—1, In the use and application of chloride of sodium (muriate of soda, or common salt) either dry, cystallized, or in a solution, as a disinfectant or deodorizer; also in the admixture with chloride of sodium (muriate of soda, or common salt), either dry, cystallized, or in a solution, of any resinous, sooty, earthy, vegetable, metallic, or alkaline matters (except oleaginous matters) as a disinfectant or deodorizer, for the purpose of deodorizing and preventing the generation and escape of noxious effluvia in refuse, organic, fecal, and urinous matters, and by so doing to remove or prevent the exhalation of the noxious effluvia. 2, The invention consists in converting such refuse, organic, fecal, and urinous matters into a concentrated portable manure, as follows:—In order to prevent the escape of the free ammonia from the excremental fecal and urinous matters in the process of manufacture, the inventors neutralize or combine the said free ammonia with the hydrochloric acid (muriate acid, or spirit of salt) of commerce, and further, by the process of evaporation in stills, pans, or boilers, by the aid of steam and hot and cold currents of air, and the application of a steam pump, for the purpose of exhausting rapidly the generated steam or vapour produced by evaporation of the fecal urinous matters in the stills, pans, or boilers. They also compound or mix with such produce the common ashes or cinders of coal, wood, peat, or other fuel collected from dwelling-houses, warehouses, offices, and works. *Patent abandoned.*

2670. T. J. Robotham. *Improvements in apparatus for purifying "glaze," "slip," or other potters' materials.* Dated October 3, 1862.

This invention consists, principally, of a vertical shaft with four or more longitudinal or inclined arms projecting therefrom, and provided with any convenient number of permanent or electro magnets, which shaft is caused to revolve (by means of any suitable gearing) in a vat or circular vessel containing the glaze or other material, so as to come into contact with, and take up every particle of, iron or other magnetic substance that may be incorporated therewith. *Patent abandoned.*

2671. R. Broadbent. *Improvements in gas regulators.* Dated October 3, 1862.

The documents relating to this invention cannot at present be seen, an extension of time for filing the final specification having been petitioned for.

2673. W. Clark. *An improved candlestick.* (A communication.) Dated October 3, 1862.

This invention relates to an improved candlestick lamp, or other similar apparatus in which the candle, taper, or oil reservoir always preserves a vertical position, whatever may be the direction in which the body of the candlestick, lamp, or holder is inclined. This improved apparatus will be found of great advantage for sea service, or in mining operations, as there is no liability to spill the oil or other fatty matter made use of, the candle or wick holder always preserving its vertical position. For this purpose, the inventor fixes a stem to the lower part of the candlestick or oil reservoir, and supplies a weight at the lower end thereof of sufficient gravity to keep the candle or other light upright. *Patent completed.*

2674. W. E. Gedge. *An improved suction and life pump, and apparatus connected therewith.* (A communication.) Dated October 3, 1862.

This pump—which may be single or double—is essentially composed of a cylindrical hollow and water-tight piston. The air which it contains communicates with the atmospheric air by small tubes; it has at its lower extremity an iron box or cup, and its packing is of gutta percha. *Patent abandoned.*

2675. A. Dalrymple. *Improvements in the processes of depositing metals by galvanic action, either with or without the aid of galvanic batteries, and in the ornamentation of metal surfaces thereby.* Dated October 3, 1862.

We cannot here quote the details of this invention. *Patent abandoned.*

2676. W. E. Gedge. *An improved marquetry or veneer saw, and machinery or apparatus connected therewith.* (A communication.) Dated October 3, 1862.

This invention consists of a marquetry or veneer saw or veneering web advantageously arranged for boring or drilling, turning, and sharpening. The saw is composed of five principal parts, which are:—A fly wheel fixed on a horizontal shaft resting on two vertical uprights; a large wheel fixed also on a horizontal shaft bent at one of its extremities to form a crank, the whole surmounted by two vertical uprights more elevated than the fly wheel; a moveable wooden plate or bed; and, lastly, a wooden pedal. The blade of the saw is about 5½ in. in its entire length, about 4 in. of which are toothed. The teeth, which are in form of a triangle, without any setting or edging, project about the 50th part of an inch, and are about the 25th part of an inch apart, which is also the entire breadth of the blade. *Patent abandoned.*

2677. T. Greenwood. *Improved machinery for cutting staves.* Dated October 3, 1862.

The object of this invention is to facilitate the operation of cutting or shaping staves from planks of wood, such staves being intended to be applied as a cylindrical covering for metal casks, and for analogous uses. To this end the patentee submits the wood to a sawing machine, which at one operation will cut the bevelled edges of the staves. The machine is provided with a double set of oblique saws, the shafts of which are inclined in opposite directions, but at the same angle; and for the purpose of bringing the cutting edges of each set on a level, or nearly so, he makes the saws of varying diameters. *Patent completed.*

2678. J. and W. Lee. *Improvements in traction engines and boilers for traction, locomotive, and other purposes.* Dated October 4, 1862.

These improvements in traction engines, under one modification, consist in giving motion to the main or driving pair of wheels by a pinion on the crank shaft of the engine gearing into an intermediate wheel, on the axis of which is another smaller wheel which gears into a toothed wheel on the axis of the main or driving wheels. The intermediate wheels turn on a stud which projects from the bracket which carries the crank shaft; this stud, the crank shaft, and the axis of the main wheels, are so placed that their centres are all in one vertical line. The improvements in boilers for traction, locomotive, and other purposes consist in constructing them so that the horizontal tubes which pass from the fire box conduct the products of combustion into a smoke box or chamber, from the top of which they pass away through vertical tubes which rise up through the dome or steam chamber of the boiler, and on the exterior of the dome the tubes open into a chimney which can be turned down when the tubes require cleaning. The smoke box or chamber above mentioned is formed by the plate which receives the ends of the horizontal tubes from the fire box, being bent at right angles, the portion bent down at right angles receiving the vertical tubes which rise up through the dome. *Patent completed.*

2679. W. H. Muntz. *Improvements in armour for the protection of ships of war, and other vessels and fortifications, from the effects of cannon shot and other projectiles.* Dated October 4, 1862.

This invention consists in protecting such vessels or fortifications by means of armour composed of elastic material which absorbs, instead of resisting, the force of the projectile, and stops it gradually instead of suddenly. This elastic armour may be made either of a solid elastic substance, such as vulcanized india-rubber, or of hollow cases or mattresses of vulcanized india-rubber, or other similar material, stuffed or filled with cotton or other elastic or compressible substance, which may be rendered incombustible by chemical means; or the cases or mattresses may be filled with atmospheric air either combustible or otherwise. The edges of the mattresses or cases should be made in the form of a scarf joint so that they overlap each other and still preserve an even surface on the exterior. *Patent abandoned.*

PROVISIONAL PROTECTIONS.

Dated Dec. 4, 1862.

3248. C. H. Roeckner, Bristol. An improved method of constructing coffer dams and other similar structures for excluding or keeping back the flow of water and preventing inundations.

Dated Feb. 9, 1863.

355. H. G. Williams and R. G. Price, Bontdu, near Dolgelly, mining engineers. An improved machine for crushing and amalgamating auriferous quartz, and pulverizing and washing ores.

Dated Feb. 11, 1862.

474. R. Saunders, Croydon, gentleman. Improvements in pavements and floors, which improvements are also applicable to stairs or steps.

Dated March 2, 1863.

580. A. F. Pagny, 15, Passage des Petites Ecuries, Paris, gentleman. A new agricultural implement for cultivating tubercles, roots, and all oil plants.

Dated March 14, 1863.

695. R. Alexander, Islington, Liverpool. Improvements in mariners' compasses, and the parts in connection therewith, and in the application thereof to magnetic instruments.

Dated March 16, 1863.

737. J. Smethurst, Royton, coal proprietor and millowner. Improvements in the construction of ships and vessels, for the purpose of obtaining additional strength and motive power.

708. W. E. Newton, 66, Chancery-lane, civil engineer. Improvements in the manufacture of iron and steel. (A communication.)

Dated March 18, 1863.

727. B. Wren, Stockton-upon-Tees, corn miller. Improvements in cleansing and treating certain descriptions of wheat and other grain.

728. E. Legris, Bondeville, France, engineer. A new or improved machine for thrashing out the seed of flax.

731. W. Lorberg, Wyld's-rents, Bermondsey, analytical chemist. Improvements in the treatment of rags, and obtaining valuable chemical products from the animal fibre therein.

Dated March 20, 1863.

743. R. Couchman, 6, Noble-street, St. Martin's-le-Grand, manufacturer. Improvements in articles or means for supporting or carrying ladies' parasols, bags, or other articles or appendages.

747. V. Houghton, 2, Merton-road, Kensington. Improvements in lamps and lamp wicks. (Partly a communication.)

Dated March 21, 1863.

756. G. A. Biddell, Ipswich, mechanical engineer. Improvements in locomotives, usually called "traction engines," to be used on common roads.

761. W. Clark, 53, Chancery-lane, engineer. Improvements in the separation or obtaining of ammonia from azoted matters in the preparation of manure. (A communication.)

Dated March 27, 1863.

806. J. D. Asquith and G. Greenwood, Morley, near Leeds. Improvements in rag machines.

Dated March 28, 1863.

812. A. Blouin, Rue du Faubourg du Temple, Paris, mechanician, and D. N. Mercier, 10, Rue Richelieu, Paris, medical doctor. An improved axle-tree, with linked levers for lifting.

Dated March 31, 1863.

830. R. A. Brooman, 166, Fleet-street, patent agent. Improvements in electric telegraph printing apparatus. (A communication.)

Dated April 1, 1863.

836. I. Rowland, Salford, Lancaster, committee clerk. An improved mileage apparatus for measuring and registering the distances public vehicles or private carriages travel.

842. G. T. Bousfield, Loughborough-park, Brixton. Improvements in steam boilers. (A communication.)

844. R. Gavin, Edinburgh, wine merchant. Improvements in the preservation of perishable liquids during the withdrawal or consumption thereof.

Dated April 2, 1863.

846. J. W. Law, and J. Inglis, Glasgow, ironfounders. Improvements in making moulds for casting, and in apparatus connected therewith.

848. D. S. Sutherland, 34, Great George-street, Westminster, civil engineer. Improvements in protecting vessels of war and fortifications from the effects of projectiles.

850. J. J. Pôtel, St. Quentin, France, engineer. Improvements in furnaces and fire-places, having for object the consumption or prevention of smoke.

852. G. A. Cox, Lochee, Dundee, jute and flax spinner and power-loom linen manufacturer. Improvements in the treatment or preparation and manufacture of jute, hemp, flax, and other fibrous or textile materials.

854. A. B. Seithen, 5, Mansfield-place, Kentish-town. Improvements in casings, covers, or wrappers for bottles, jars, and other articles.

Dated April 4, 1863.

858. J. Silvester, West Bromwich, manufacturer. Improvements in attaching guards to pressure gauges.

860. W. E. Gedge, 11, Wellington-street, Strand. Improved apparatus for bolting flour. (A communication.)

862. A. V. Newton, 66, Chancery-lane, mechanical draughtsman. An improved construction of pressure guaga. (A communication.)

Dated April 6, 1863.

864. F. C. Bakewell, 6, Haverstock-terrace, Hampstead. Improvements in wicks for lamps. (A communication.)

866. T. Burrow, Albert-place, Brighouse, near Normanton, York, silk spinner. Improvements in, and machinery for, combing or dressing silk, flax, wool, hemp, China grass, or other fibrous materials.

868. M. Henry, 84, Fleet-street. Improvements in probes, catheters, and similar surgical instruments. (A communication.)

870. J. Burwin, Keighley, shuttle and picker manufacturer. Improvements in pickers, and in the means or apparatus employed in the manufacture thereof.

Dated April 7, 1863.

874. A. C. Bamlett, Ripon, agricultural engineer. Improvements in reaping and mowing machines.

878. R. A. Brooman, 166, Fleet-street. Improvements in the manufacture of baryta and its derivatives, in obtaining by-products, and in revivifying or recovering certain agents employed in such manufacture. (A communication.)

Dated April 8, 1863.

882. G. H. and W. R. Hill, Bolton, boiler makers. Improvements in steam boilers.

884. J. Mosheimer, Dolgelly, gentleman. Certain improvements in machinery or apparatus for crushing, grinding, and dressing metallic ores, quartz, and other similar substances.

888. W. E. Gedge, 11, Wellington-street, Strand. Improvements in apparatus for propelling and navigating small craft. (A communication.)

890. J. L. Norton, Belle Sauvage-yard, Ludgate hill. Improvements in machinery for washing and drying wool and other fibres and rags.

Dated April 9, 1863.

892. H. B. Fox, Liverpool, Lancaster. Improvements in dish covers.

902. A. V. Newton, 66, Chancery-lane, mechanical draughtsman. An improved construction of offensive weapon. (A communication.)

904. A. V. Newton, 66, Chancery-lane, mechanical draughtsman. An improvement in stirrups, and in the mode of attaching the same to saddles. (A communication.)

PATENT APPLIED FOR WITH COMPLETE SPECIFICATION.

Dated April 10, 1863.

906. S. A. Couperie, Bordeaux, France, gentleman. A semicircular metallic slide, whereby the pole bolt is effectually suppressed, and which can be adapted to every four-wheeled vehicle.

NOTICES OF INTENTION TO PROCEED WITH PATENTS.

From the *London Gazette*, April 21, 1863.

3273. G. Wright. Food for cattle.

3288. C. Sanderson. Manufacturing bands for driving machinery.

3292. E. T. Hughes. Galvanic apparatus. (A communication.)

3303. P. Effertz. Making bricks, tiles, and drain pipes.

3304. W. E. Newton. Firearms. (A communication.)

3313. D. Chalmers. Manufacture of textile materials.

3316. J. King. Signalling.

3317. E. Toynbee. Extracting oils and fatty matters.

3319. W. Tristram and H. Brereton. Sizing yarns and threads.

3320. J. R. Breckon and T. Douglas. Manufacture of firebricks.

3321. R. A. Ronald. Printing textile and felted fabrics.

3325. W. Goulding. Ploughs.

3330. J. Gaskell and H. Walmsley. Regulating the tension of yarn in the processes of warping, winding, sizing, weaving, and other similar purposes.

3334. S. Fox. Manufacture of gas.

3344. M. Henry. Propellers. (A communication.)

3345. M. J. Roberts. Preparing and spinning fibrous substances.

3349. W. Phelps. Locks.

3354. J. Varley and J. Crowther. Steam engines.

3365. R. Hattersley. Classing printers' types for composing machines.

3367. A. Albini. Breach-loading firearms.

3372. J. Ramsbottom and G. Hacking. Measuring and registering the flow of water and other fluids.

3373. J. W. Hadwen. Spinning, twisting, and doubling fibrous materials.

3375. F. De Wyldé. Improved means for the protection and preservation of lead surfaces exposed to the action of water. (A communication.)

3378. L. Latter. Ploughs.

3381. J. Clayton. Furnaces for heating large masses of iron and steel.

3389. J. Pernod. Purpurine.

3391. J. Longland. Street lamps.

3394. I. Holden. Preparing and combing fibres.

3395. I. Holden. Washing fibres.

3401. J. Dalton. Knitting machinery.

3404. A. T. Blakely. Breech-loading ordnance.

3419. J. B. Dalhoff. Cutting files.

3432. G. H. Birkbeck. Surveying and levelling. (A communication.)

3435. A. P. Tronchon. Firearms.

3439. W. Clark. Applying heat. (A communication.)

3452. W. Clark. Firearms. (A communication.)

3471. J. Robson, jun. Stove grates.

1. R. H. Collyer. Manufacture of paper and similar purposes.

84. M. Henry. Furnaces. (A communication.)

97. W. Clark. Preparations of green colouring matter. (A communication.)

110. C. E. Amos. Manufacture of paper.

140. A. Prince. Sewing machines.

177. J. W. Meears. Sash frames and sashes.

417. W. C. McEntee and T. Withers. Locks.

654. Sir A. Keller. Reeling silk direct from cocoons on bobbins.

674. F. B. Kraushaar. Winding, cleaning, measuring, sorting, doubling, throwing, and reeling silk.

717. G. De Laire. Manufacture of brown colouring matters. (A communication.)

752. F. De Wyldé. Cement from gypsum.

764. W. Johnson. Lighting and heating.

765. T. G. Grant. Ovens and apparatus.

862. G. A. Cox. Manufacture of fibrous or textile materials.

878. R. A. Brooman. Manufacture of baryta and its derivatives. (A communication.)

The full titles of the patents in the above list can be ascertained by referring back to their numbers in the list of provisional protections previously published.

Opposition can be entered to the granting of a patent to any of the parties in the above list who have given notice of their intention to proceed, within twenty-one days from the date of the *Gazette* in which the notice appears, by leaving at the Commissioners' office particulars in writing of the objection to the application.

LIST OF SEALED PATENTS.

Sealed April 17, 1863.

2814. R. A. Brooman.
2816. W. E. Gedge.
2819. G. Haseltine.
2821. J. Clark.
2823. W. A. Turner and T. T. Coughin.
2825. H. L. Emery.
2826. J. H. Johnson.
2831. S. Witham and T. Wright.
2832. C. G. Clarke.
2834. J. T. Cooke.
2835. R. A. Brooman.
2838. G. Haseltine.
2840. C. T. and F. C. Belhomme.
2842. J. Spence.
2848. T. Fearn.
2860. E. H. Carbutt and G. A. Clough.
2887. F. Lipscombe.
2909. G. Darlington.
2912. W. Clark.
2939. G. Dickinson and E. Cooke.
2946. G. Speight.
2965. L. Gonez.

LONDON, FRIDAY, MAY 1, 1863.

WATER-GAUGES.

Although it is quite certain that a red-hot fire-box cannot generate sufficient steam to explode a boiler, it is equally certain that any over-heating due to too low a water level, is not only injurious, but, if often repeated, absolutely destructive to either the bottom plates of a boiler, or the top of a fire-box, as the case may be; hence a few words on the best means of ascertaining at all times the precise level of the water within a boiler, may not prove uninteresting.

Were it possible to construct a boiler of glass, many phenomena doubtless, connected with the relative generative powers of different regions of the boiler, the mode in which priming takes place, the deposit of sediment &c., would become so evident to a careful observer, that many useful deductions might be drawn from the information so gained; but as boilers are invariably constructed of opaque materials, all information regarding the state of affairs within, must be described from sources more or less indirect. A patent has, it is true, been taken out for the application of a powerful lens—or telescope, in fact—by means of which the observer, aided with a strong light cast within the boiler, by a lamp and a second lens, can wholly or partially learn all that goes on within; such an invention not being likely to meet with very general adoption, we need not dwell further on its merits or demerits, but turn to those water-gauges met with in daily use.

The first we have any mention of in the history of the steam engine is the single gauge, cocks, first applied by Savery in the year 1698. Its application was sufficiently obvious—it was merely making a hole in the side of a vessel through which water would flow when it had reached it. Shortly afterwards Savery employed two of these cocks in order that the water level might be ascertained with greater accuracy. These gauge-cocks are in use to the present day, but, in our opinion, frequently do more harm than good; it is almost impossible, when the steam is of any considerable pressure, to ascertain whether water or steam escapes from them. Water, by its contained heat, is almost instantly dissipated in spray and steam when the lower cock is opened; and as it always rises to any opening near its level, the upper cock will discharge it plentifully, even though the real water level is at the instant several inches below it; hence they are almost totally useless for tubular boilers, unless we adopt some such arrangement as that employed by Mr. Gooch in some of his locomotives. He affixed a brass tube of small diameter to the boiler in exactly the same way that a glass guage is fitted; into this tube the gauge-cocks are screwed. In order to test the level of the water, open both cocks communicating with the vertical pipe for a few minutes, then close them, and open a small cock on the top of the tube, which will discharge the steam contained in it; then, on opening the gauge-cocks, the exact level of the water within the tube, and of course within the boiler, may be ascertained with certainty as the water issues quietly by its own gravity from the gauge-cocks.

The ordinary gauge-cocks may sometimes be applied with propriety to large boilers without inside flues, as the variation of the water level through a range of nine or ten inches, is seldom of much importance, and in many situations where boilers get little cared for and glass gauges are liable to be broken, they possess a certain amount of value.

But the most popular gauge for such situations, and indeed the only one used in many parts of England, is the float; only applicable to stationary boilers, of course. This, if properly constructed at first, and treated with moderate care afterwards, we are inclined to consider second to none; its cleanliness, and the large range of indication which it gives, render it an extremely valuable instrument; but, when badly constructed and neglected for long periods, it is undoubtedly more likely to give false indications than the glass water-gauge. The most usual arrangement is a stone float suspended from a wire, which, passing through a stuffing-box, is attached to a small chain, which runs over a light iron pulley, a foot or more in diameter—the other end of the chain carrying a weight which partly balances the stone within the boiler, so as to keep it floating; but as the stone is seldom very large, and acts directly on the wire, it is very easy, by screwing the gland of the stuffing-box too tight, to render it altogether inoperative. The use of iron wire in such a situation, will also be certain to induce corrosion, and the consequent destruction of the stuffing in the box.

The proper method of fitting a float is undoubtedly the following:—Let a lever of considerable length be hung on a fulcrum within the boiler; one end of this lever must be so bent as to reach above the water level, and must carry a cast-iron ball, sufficiently heavy to balance enough of the weight of a float, moulded and burned in hard brick, fixed to the other end, that it shall be only half immersed in the water. Outside the boiler a light index lever must be fitted, to the short end of which a fine brass wire is attached, and being passed through a small brass stuffing-box, is fastened to the float lever within the boiler close to the fulcrum; any amount of friction in the stuffing-box can scarcely affect the action of the float, from its powerful leverage; and the light index outside can be made to traverse through a sufficient distance to show the most minute variations in the water level.

A very efficient float indicator can also be made by fixing a hollow ball sufficiently strong to stand the pressure, and light enough to float, on the end of a lever, of very considerable length, which will lie parallel to the axis of the boiler. The fulcrum of the lever must consist of a brass ball fitted into a stuffing-box on the boiler end, the lever being prolonged a few inches through the stuffing-box, and attached as before to a suitable index. It would be impossible, from its great leverage, to set this float fast, no matter how tightly the packing might be screwed down, and a good india-rubber stuffing would last many months, owing to the almost inappreciable amount of motion in the ball. Such a gauge would, we have no doubt, be certain in its action, and could scarcely get out of order.
